The degradation process in biopiles generally takes several months. All of the 81 stationary large-scale biological soil treatment plants in Germany use the biopile procedure. Figure 26 shows an example of the biological treatment of soils contaminated with petroleum hydrocarbons and polycyclic aromatic hydrocarbons according to the Terraferm process in roofed piles by Umweltschutz Nord. This process is used at 11 stationary biological treatment plants in Germany.

Figure 26. Terraferm heap process of Umweltschutz Nord for the biological treatment of soils contaminated with petroleum hydrocarbons and polycyclic aromatic hydrocarbons in Frankfurt/Main

In the microbiological in situ procedures, the soil is not excavated. Depending on the depth of contamination, different in situ methods are possible. In the case of *superficial contaminations* in the unsaturated zone soil can be loosened up in order to make it possible to add nutrients or water to create optimum environmental conditions (landfarming).

In the case of *deep-seated contaminations*, infiltration of microorganisms and nutrients through a rinsing cycle in combination with hydraulic measures are used.

However, the applications of biological in situ processes are relatively limited compared to on-site/off-site processes. The site is not usable during the relatively long period of remediation and in many cases, the in situ boundary conditions (inhomogeneous pollutant distribution, deficient hydraulic conductivities, inadequate moisture and oxygen conditions, unfavorable conditions of temperature and pH) are such that on-site biological treatment, like biopiles or other measures are preferred. As a rule, suitability of in situ biological treatment depends on the bioavailability of pollutants in the soil, their microbial degradability, and certain soil qualities (homogeneity, content of fine grains). Table 39 shows the microbial degradability of substances classes, provided that these substances are bioavailable.

Table 39. Microbial degradability of substances relevant for decontamination

Class of substances	In principle, easily degradable	In principle, difficult to degrade
Aliphatic hydrocarbons, petroleum hydrocarbons and their derivatives	+	
Monocyclic aromatic (e.g., BTX aro-matics) and heterocyclic hydrocarbons (e.g., pyridine, quinoline)	+	
Polycyclic aromatic hydrocarbons (PAH)	+[a]	
Highly volatile halogenated — in particular chlorinated — hydrocarbons	+	+[b]
Alicyclic chlorinated hydrocarbons and their derivatives	+	
Polychlorinated biphenyls (PCB)		+[c]
Polychlorinated dibenzodioxins and dibenzofurans (PCDD and PCDF)		+[c]
Pesticides and their derivatives		+[c]
Heavy metals		not degradable

[a] Up to ring 4 PAH.
[b] Ring 5 and 6 PAH, trichloroethylene, polychloroethylene (PCE).
[c] Some low-chlorinated congeners are in principle degradable/dehalogenatable. For highly chlorinated congeners degradation cannot be confirmed at present.

7.1.2.2.4. Soil Vapor Extraction Processes

Soil vapor extraction procedures are applied for the remediation of soils that are contaminated with highly volatile compounds. These extraction procedures are primarily applied in the unsaturated zone of the soil as in situ processes. The contaminated soil vapor is extracted by a low pressure, generated by a vacuum well. At the same time, evaporation is promoted by increasing the flow of air along the pollutant molecules. The exhausted soil vapor is purified by activated carbon.

Soil vapor extraction can be combined with air sparging of the saturated zone. The pressurized air introduced into the groundwater causes a stripping process and thus converts the volatile pollutants to gas. The gaseous pollutants are collected and extracted by the soil vapor extraction device and decontaminated with activated carbon.

Soil vapor extraction has been used very successfully for a long time on a large scale for the remediation of soil contaminated with volatile compounds (volatile halogenated hydrocarbons, aromatic hydrocarbons, gasoline hydrocarbons). The advantage of this process is that high purification capacities can be achieved with relatively simple design. Figure 27 shows a soil vapor extraction arrangement for the remediation of underground contamination at a plant site. The compact system, consisting of an exhaustion unit with water separator, electrical control unit, and an activated carbon filter, has only a small space requirement.

Figure 27. Compact plant for soil vapor extraction (HUT company) on a plant site

7.1.2.3. *Safeguarding Technologies*

Surface sealing systems seal off the contaminated soil from atmospheric influence. Thus, they prevent infiltration of rain water in the contaminated areas and leaching/migration of pollutants into groundwater. Surface sealing systems consist of the actual sealing component, surface water, and gas drainages.

Vertical sealing systems are mostly carried out as slurry walls. Slurry walls are designed to seal off the contaminated soil from the surrounding and thus prevent lateral leaching of pollutants. They are inserted up to a depth where a natural compact layer is present; in combination with surface sealing they encapsulate the contaminated soil.

The requirements for the type and the mass of the slurry wall are determined for each individual case, depending on the chemical and hydraulic strain. The most common types of slurry walls are sheet walls, thin walls, and diaphragm walls.

Immobilization Measures. With immobilization measures, the pollutants in the soil are contained in such a way that leaching into the environment is prevented or reduced. Although various immobilization processes are available (compaction, sealing, canopy, etc.), in most cases processes for pollutant stabilization by solidification are applied for the treatment of contaminated soil. In the solidification process, the contaminated material is mixed with a bonding agent and water and then filled into molds; or installed and compacted on the spot; or pressed into molds and pelletized. This process is aimed at manufacturing a water-proof and solid monolith as final product of the solidification process.

There is no best available technology for solidification procedures with qualitative requirements for the solidified material. The following criteria are used to determine the suitability of solidification procedures:

mixed contamination of soil,
low to medium organic contamination,
low to high organic contamination,
fine-grain material.

The suitability has to be tested in advance.

Passive Hydraulic and Pneumatic Measures. *Hydraulic measures* have been the most frequently used technology in hydraulic engineering and foundation engineering for a long time. These measures are employed to prevent contact between the contaminated material and the groundwater. This is achieved by changing the hydrodynamic situation of the groundwater, for example by lowering the groundwater level with extraction wells or reversing the groundwater flow with infiltration wells. Hydraulic measures are used for existing depositions and hazardous waste sites.

In contrast to that, *pneumatic measures* are only relevant for existing depositions that form a hazardous gaseous phase. Pneumatic measures imply installing a gas drainage to control the disposal of gas and thus to prevent the gas from migrating into the surrounding.

7.1.3. ***Costs for Soil Remediation***

As a matter of fact, the costs incurred for soil decontamination in Germany are strongly influenced by the market conditions, i.e., by the treatment capacities offered and the amount of soil that is made available for decontamination. As previously mentioned, in Germany the available treatment capacity already exceeds the request for soil cleaning. Consequently, competition strongly influences the costs for soil treatment. In 1990 the companies charged for the clean up of 1 t of contaminated soil about

$ 150 – 300 for thermal treatment
$ 120 – 200 for soil washing
$ 100 – 200 for biological treatment

Since then, the prices for soil decontamination have decreased significantly, as the figures from Germany from June 1998 indicate. Table 40 reflects the results of a survey on the costs of the main decontamination techniques for three defined types of soil [399] (3000 t soil, moisture content 15 % contamination profile given as PAHs and TPH (Total Petroleum Hydrocarbons).

The costs for *soil washing* are constantly falling, but rather slowly. The upper limit of cost in terms of an economic operation of this technique seems to be reached. The same is true for *thermal treatment*. However the cost for the thermal treatment of lightly contaminated soil are now on the same reasonable level as the biological treatment.

Table 40. Costs for soil treatment in Germany

	Average costs in 1995, €/t			Average costs in 1996, €/t			Average costs in 1997, €/t			Average costs in 1998, €/t		
Type of soil	**Thermal treatment**	**Soil washing**	**Biological treatment**	**Thermal treatment**	**Soil washing**	**Biological treatment**	**Thermal treatment**	**Soil washing**	**Biological treatment**	**Thermal treatment**	**Soil washing**	**Biological treatment**
Contaminated soil type 1[a]	121	124	75	111	112	70	97	100	62	90	93	56
Contaminated soil type 2[b]	101	96	75	94	86	67	84	81	54	84	68	51
Contaminated soil type 3[c]	81	83	64	74	75	56	83	64	46	83	53	38

[a] Fine grain content < 30 %, PAH 2000 ppm, TPC 10 000 ppm.
[b] Fine grain content 15 %, PAH 200 ppm, TPC 5000 ppm.
[c] Fine grain content: 15 %, PAH none, TPC. 5000 ppm.

7.1.4. ***Outlook***

In Germany, the standard for the treatment of contaminated soil is relatively high. Expenses spent by the public sector for research and development are estimated being added up to 153×10^6 € for about 200 projects within the last 20 years. Industry has invested approximately 460×10^6 € only for soil decontamination. Meanwhile, there are more than 100 soil treatment plants in operation providing a total treatment capacity of almost 4×10^6 t/a. Further development of soil decontamination technologies will be restricted to very specific problems like the biological treatment of TNT or TNT derived compounds. While during the 1980 and in the first half of the 1990s the main remediation strategy had been focused on soil decontamination, nowadays the approaches move to a broader concept. Land remediation must be seen in a close relation to the reuse of land. In this context, land remediation is not only the elimination of dangers by the clean-up of soil and groundwater. Besides the purification it encompasses the whole process of land development for future uses. This means, the remediation or reclamation process will become more complex and interdisciplinary.

7.2. Recultivation

7.2.1. ***Definition***

The term *recultivation* has become established as a collective name for all human activities for the restoration of a landscape. Following definition is given in [404]: “Recultivation denotes all the initiatives and measures that serve for the restoration of the scenic and economic structure of those parts of the cultivated land whose natural productivity have been considerably reduced or destroyed by human interventions, primarily by the mining of raw materials.” In this definition the economic, ecological, and structural factors are regarded as of equal rank.

The term *renaturation* has been introduced for the treatment and development of abandoned mining areas, preference here being given to free succession without significant additional shaping of the landscape. As a rule, renaturation areas are small. In recultivation, by contrast, various, extensive landscape elements are combined with one another. At the same time the main characteristics of the cultivated land — that is its settlement and use by human beings — are deliberately incorporated.

Successional processes are integrated also in the modern notion of recultivation. If a certain nature conservation goal has to be followed, priority is given to the taking over of geological and ecological conditions exposed by mining or to the conscious shaping with initial substrata that are not immediately cultivable. A landscape made largely uniform by agriculture and forestry, especially in Central Europe, can require this.

7.2.2. *Demands on Recultivation*

The mining of raw materials is usually accompanied by a radical change of the earth's surface, and ecological equilibria that have become established over thousands of years and have been more or less modified by human use are destroyed. For this reason the ultimate goal of recultivation is considered the restoration of a balanced ecological state and fitting of the recultivated area into the surrounding landscape. Negative examples from many countries of the world show that this cannot be achieved without a target for soil development or establishing an ecologically compatible chemical and physical state. Those examples include the tertiary sand waste heaps of the former East German lignite open mines, the erosion-threatened and nutrient-free dumps of lateritic soils in Asia, and the heavymetals contents of waste materials from mines worldwide.

7.2.2.1. *Recultivation Goals*

The recultivation goals for mined areas have to be as various as the settlement, industrial, and countryside areas concerned themselves. However, some basic principles can be generalized:

1. Recultivation, in contrast to renaturation, requires such a large area of land that its organization becomes the subject of district planning and regional planning procedures. Recultivation thus becomes a task of regional policy and is therefore exposed to political processes even in the goal setting.
2. Interventions in the economic area necessitate interference with property. Depending on the initial situation, decisive courses are often set here. Thus, in former West Germany, for example, clear preferences exist for the reestablishment of agricultural or subsequent commercial uses.
3. The nature of the intervention to be compensated for, especially its technical or commercial layout, creates far-reaching conditions that exclude particular recultivation goals and favor others. If, for example, the landscape is changed by the creation of inner and outer dumps, only woods can be planted because of the resulting slopes, especially also with regard to the erosion dangers. Microclimatic changes due to the intervention also occur, but their influence is weaker. Furthermore, the leaving of final voids will inevitably lead to formation of water bodies. Altogether, changes of the groundwater conditions are far-reaching for the shaping of the landscape in certain regions of the world.
4. Important factors for the formulation of the recultivation goal are the geological conditions and thereby the possibility of selecting adequate soils. The lignite commission mining plans in former West Germany, which were drawn up for the Rhenish lignite district, can serve as examples for the drawing up of recultivation goals.

In the Rhineland, in accordance with land use before coal mining, attention is centered on *agricultural* reutilization. With this, the careful choice of initial substrate and the development of soil fertility become very demanding tasks. The application of the tillable cultivated layer, mostly consisting of loess or loam, is followed by seven years of interim farming, which leads, via the first sowing and maintenance of alfalfa, after three years to the main crops barley, wheat, rye and sugar beet or even vegetables.

In the winning of other raw materials, agricultural recultivation after termination of extraction is not an attainable goal anyway, since no soil substrata at all are available originally: examples are the hard coal heaps which even after applying native soil, merely allow planting with trees or grasses, but on the other hand are well suitable for the restoration of recreation areas.

In other climates, especially in the tropics, agricultural recultivation is started best with agroforestry, especially in order to remove the initial food bottlenecks and solve the erosion problems.

For *reafforestation*, a much wider range of different substrata can be used because of the greater ranges of site requirements of the wood plants.

For the *moderate climatic regions of former West Germany*, determined by loam – gravel soils, the possibilities of forestry can be described with the following types of management objective.

1. Common oak – small-leaved lime – hornbeam mixed forests with transitions to sessile oak forest on dry locations, 40 % of recultivated area
2. Beech forests with strong inclusion of valuable broad-leaved trees (e.g., ash, red oak, walnut, lime, maple, and common elder) and a minor amount of European larches, 30 %
3. Deciduous forests with a high proportion of valuable broad-leaved trees distributed in groups or small stands, 10 %
4. Coniferous woods, principally Douglas fir, but also pine and fir, 10 %
5. Meadows, succession areas, hedges, bodies of water, 10 %

Things are quite different in the drier and sandy *East German recultivation areas*. In former East Germany the following types definitely predominate:

1. Pine – sessile oak forest
2. Pine – common oak forest
3. Birch – heath succession stages

Water bodies can be laid out as a further important building block of recultivation landscapes. These bodies of water can be economically important as retention areas, but in arid regions they take over the important function of water reservoirs. Water bodies are regarded in Central Europe as undesirable for water management owing to the exposure of the groundwater strata and the risk of entry of substances. As recreation areas and above all as nature conservation areas, however, they are outstandingly important. If recultivation areas are declared as national preserves in former West and East Germany this is based mostly on the wealth of species on the bodies of water.

Owing to the enormous decline of species in the cultivated land it must be assumed that at least 10 % of the recultivated area are used for the protection of species in highly developed settlement and economic areas. In other areas, e.g. in former East Germany, that have a considerably smaller demand for agricultural use, the proportion of areas used for the protection of endangered species amounts to more than 50 % of the total area. By this means recultivation comes ever closer to its goal of being a compensation for an intervention in the ecosystem.

7.2.2.2. *Initial Substrata*

A key role in recultivation planning attaches to the analysis and selection of the geological strata exposed during mining. Materials from great depths often have on the one hand advantages in nutrient content and grain size structure, but on the other hand outright poverty or absence of biogenic contents. As a rule, a topsoil application is impossible for technical reasons. The main problem in this connection is that because bulldozers and lorries must be used for the application of topsoil, the possible positive effects are nullified again by soil compaction.

The displacement process inevitably entails the destruction of the live substratum “soil” and its specific bedding. The recultivation cannot start to develop a pedosystem and finally an ecosystem from spent soils but merely from introduced substrata.

For Europe, three initial materials in particular play an important part: loess and loess loam; river gravel; Pleistocene sands and marl.

Loess is a yellow-brown to gray-brown, limey, eolian loose sediment from the dry-cold climatic phases of the Pleistocene. Over a period of about 20 000 years, the upper layer of this silt-rich material has developed through pedogenetic processes (clay formation, clay displacement, deliming) as a rule to para-brown earths, similigleys (including their transitional phases) and, if groundwater influence is present, to gleys.

This loess loam grades downward into lime-rich, loose loess. Until into the present century, this loose loess was extracted as an agricultural fertilizer in small underground “marl pits”. Below this “marl” there follows a layer, of Riss date, of carbonate-poor, partly clayey or sandy-gravelly loam.

This stratigraphic sequence found in the Rhineland is of variable thickness, because during the deposit of wind-borne loess erosion phenomena also naturally occurred, and may occasionally have removed a whole bed again.

The terrace sediments lying under the loess beds are melt water deposits (sands, gravels, and boulder flint) from the Pleistocene. Also found are oligotrophic, weakly sorbing clays from the Tertiary, consisting mainly of kaolinite.

7.2.3. *Soil-Physical Properties*

7.2.3.1. *Silvicultural Recultivation*

The investigations carried out by the State Geological Office of North Rhine-Westphalia led in 1967 to the laying-down of directions on the application of tillable soil material for silvicultural recultivation in the lignite districts of the Rhineland. After a certain trial period, these directions were revised in 1973, 1984 and finally once more in 1996 in order also to support a larger variety of different soil substrates. Thus the variation of ecological stations is increased.

The essential elements of the directions are: the rough heaps must be so shaped that no water damage or damming occurs. Their top 1 – 2 m should consist of sufficiently permeable sandy – gravelly material. Tillable soil material should be applied about 3 – 5 m thick on the rough heap. Possible tillable material is a mixture of sandy – gravelly beds of the high and middle terraces and loess or other cohesive types of soil called forest gravel. Also usable are highly loamified loesses unsuitable for agricultural recultivation as well as loess beds affected by groundwater and dam water. On level or gently inclined surfaces the tillable material should include 25 – 66 % of loess or loess loam. On slopes (i.e., areas of an inclination exceeding 1 : 3) the loess fraction should be limited to 20 – 25 %. Instead of a 4 m thick mixture of loam and gravel, 2 m of loess or loess loam also can be dumped. Processing the surface thus applied with earthworking machines is not required.

After the last revision of these directions it is also allowed to use pure sand or clay and different other substrates on small areas in order to increase pedological variability.

In 1984, STRATMANN carried out profitability studies on recultivation areas in the Rhenish lignite district for the Niedersächsische Forstliche Versuchsanstalt (Lower Saxony Forestry Research Institute) [405]. One of the purposes of the investigation was to assess in detail the relationships between tree growth and soil. The soils included were mixtures of gravels and loams: i.e., substrata that corresponded to the instructions of the State Supreme Office of Mining for the Rhineland, even if these came from times when the directives for the

deliberate blending of such mixtures were not yet laid down. However, among others locations with pure loams, sands, and silts having more or less small additions of fly-ash and coal were also investigated.

According to the results, the prospects for future oak cultivation on forest gravel must be judged favorable. In accordance with the specific site requirements of the two oak species, the sessile oak should be placed on the drier sites and the common oak on the wetter. The hornbeam or the small-leaved lime can be mixed in instead of the beech for the clearing of the stems.

In the final assessment it is stated that sandy forest gravels can lead to a considerable reduction of the yield of forest stands. Soil compaction significantly restricts the growth. The effects of soil compaction were investigated in detail in the following years. On spreading the forest gravel, more or less strongly marked ridges arise which, according to forestry opinion of the 1970s, had to be removed by leveling. The standards of the final operation schedules (especially the required slope inclinations) made in many areas an enormous amount of leveling necessary; and the resulting compactions, which in some cases were high, could not be removed satisfactorily, even by subsequent ripping.

The compactness of the forest gravel was subjected to a detailed investigation. Finally the decision was made to preferably dump the material such that small ridge heights are obtained and leveling is therefore omitted [406]. The tipped substrata then have the highest possible pore volumes which gives the best prerequisites for good rooting, a sufficient water storage and subsequent water supply, as well as an assured gas exchange for plant growth.

The basis of these considerations was that each excavation process destroys the soil structure, and as a result of the deposition of both loess and boulder gravel, a coherent structure that tends to instability or *compaction* is finally formed. This relates especially to compaction of the coarse pores, whereas the distribution of the fine pores is little changed.

The total pore volume fluctuates between 40 and 25 %, forest gravels of high loam content show relatively high pore volumes. The influence of the leveling operation was investigated and established in detail [407]. It is interesting that merely a single aftertreatment shows a positive effect, while several operations are again accompanied by negative compaction effects (Table 41).

Table 41. Effects of various forms of tillage before afforestation on soil structure, void ratios per measuring depth

	Surface			
	Leveled, ripped and harrowed	Leveled, ripped and smoothed	Leveled, ripped	Small spreader, not treated
Measuring points	1 – 8	1 – 6	1 – 6	1 – 6
Depth	Void ratio %			
0.3 m	30.1 ± 2.9	28.0 ± 1.9	29.2 ± 1.0	35.2 ± 1.0
0.6 m	27.7 ± 2.6	27.8 ± 1.2	29.0 ± 2.3	33.5 ± 3.5
0.9 m	28.1 ± 2.5	28.3 ± 1.5	30.5 ± 2.4	35.3 ± 1.1
1.2 m	28.5 ± 3.0	30.1 ± 1.5	32.5 ± 1.8	35.0 ± 3.5

It remains to be seen whether the better starting conditions on unleveled forest soils persist: future research will have to keep an eye especially on the biological regeneration and structuring of the soils. Previous investigations show that there is apparently a connection between amount of initial compactness and earthworm settlement.

In forest gravel investigations the compactness ranges from 1.5 – 2 g/cm^3, and therefore approaches that of pure main terrace gravels. Forest gravels richer in loess, with their densities of 1.7 – 1.85 g/cm^3, correspond to the old forest sites on similigleys.

Recultivation soils must be generally classified as “dense” to “very dense”, an increase of loess and loam fractions enhances pore space and loosening. For typical physical soil characteristics see Table 42.

Table 42. Most frequent values for consolidation, pore volume and void ratio of the soils (105°C dry)

Soil type	Consolidation, g/cm^3	Pore volume, %	Void ratio (or ϵ)*
Sandy	1.67 – 1.19	37 – 55	0.58 – 1.22
Loamy	1.96 – 1.19	26 – 55	0.25 – 1.22
Silty	1.53 – 1.19	42 – 55	0.72 – 1.22
Clayey	1.32 – 0.92	50 – 65	1.00 – 1.85
Organic	0.48 – 0.12	60 – 90	1.50 – 9.00

* ϵ = porosity.

A peculiarity shown in the investigations on forest gravel was a strong tendency to a natural compaction of the materials when the admixture of loams and loesses in the forest gravel was such that the proportion of cohesive components taken up was between 15 and 18 % [407]. In these cases a complete filling of the pore space can be assumed due to the composition and grain size of the material, so that compaction occurs even without fairly strong external action.

The investigations in the Rhineland show that with loess, but in the end also with forest gravel with the appropriate admixture of cohesive components, the moisture of the material to be excavated is of great importance. It is generally accepted that wet areas should not be excavated. Wet areas are also often encountered where as a result of preliminary work soil materials are stockpiled and are then wetted for a fairly long period. The materials scarcely release this moisture even after digging.

The erosion risk on the numerous slopes leads to the conclusion that the forest gravels should contain a maximum of 25 % of cohesive components. However, investigations in open pits that have limey loess available showed, that on increasing the lime content of the admixed loess the stability of the forest gravel increases considerably even on the slopes, so that 30 – 40 % admixtures of loess in the forest gravel are acceptable without considerable erosion problems occurring.

7.2.3.2. *Agricultural Recultivation*

The greatest demands on the choice of soil naturally arise for agricultural recultivation. If loess materials are available, it is clearly preferable here to feed them into the agricultural recultivation. The following procedure has been successful [408]. The quality of the loess to be spread is analyzed by sampling the mining slope and hand drilling in the zone immediately in front of the working boundary. During the building up of the rough heaps and the spreading of the loess, technical aids are used (e.g., rotary lasers) in order to produce the most accurate possible surface even with the high-capacity equipment and to minimize the leveling expenditure. Bulldozers with extremely low specific soil pressure are used. In the loess leveling of the arable land, surface roughnesses can be allowed to remain, provided they do not prevent subsequent treatment with agricultural machines. The loess must not be leveled immediately after spreading, but only after complete drying out. To obtain a small ridge height during the spreading of the loess, high-capacity equipment must be operated at reduced power, if required. Wherever possible the dumping height of the topmost spreader must be so reduced that a horizontal position of the discharge boom is maintained. By this means a more precise filling is made possible.

The questions of the aeration and rooting of the soil are most important, especially in the technical design of the measures. The comparison of yield between old and new land allows a positive assessment of the loess recultivations (Table 43). The variation of the basic soil-physical data in loess recultivations has been pointed out [409] (see below):

Soil type and grain size distribution	lU (medium-loamy silt) with 14 – 17 % clay, 70 – 80 % silt, 2 – 5 % sand
Humus content	0.5 to >1.0 %; average increase ca. 0.03 %/a
Bulk density	1.55 – 1.75 g/cm^3
Total pore volume	35 – 52 vol %
Proportion of airconveying voids (>30 µm)	4 to >12 vol %
Utilizable water capacity relative to 1 m root space	high, 160 to >200 L/m^2
Consistency limits	
yield point	26.0 – 29.0 wt %
plastic limit	18.0 – 22.0 wt %

plasticity index	5.5 – 8.0 wt %
shrinkage limit	5.0 – 10.0 wt %

Table 43. Comparison of crop yields on recultivated areas and neighboring old land in Neuss county (t/ha)

Crop type	1990		1991	
	Recultivated area	Old land	Recultivated area	Old land
Wheat	6.1	7.1	8.5	8.5
Rye	5.4	6.1	6.7	6.0
Barley	6.3	5.1	6.9	6.8
Rape	4.1	3.1	4.2	4.0
Sugar beet	71.4	58.6	66.0	58.4

The suitability of different starting materials for different recultivation goals is shown in Table 44.

Table 44. Use of various substrates

	Loess			Marl	Pleistocene river gravel	Pleistocene sands	Tertiary sands	Clay	Marl – sand mixture	Loess – gravel mixture
	Parabrown earth	Similigley – gley	Carbonate-containing underlying loess							
Agriculture	x	▪	x	▪	o	▪	o	o	▪	o
Forestry	x	x	x	o	o	x	o	o	x	x
Protection of species	x	x	x	x	x	x	▪	x	x	x
Recreation areas	x	▪	x	▪	o	x	o	o	x	x

x = suitable; ▪ = of limited suitability; ○ = unsuitable.

7.2.4. *Soil-Chemical Properties*

7.2.4.1. *Silvicultural Recultivation*

Investigations on nutrients content at various problem sites and on nutrient uptake by their vegetation have yielded fundamental information.

Thus it has been found for oaks and beeches on comparable difficult stands that as regards soil nutrient supply, only a few nutrients such as phosphorus and magnesium showed a deficiency. In addition, the pH values were too low in many cases, because at the problem sites the forest gravels were usually very poor in loam and loess. The leaf nutrient values found there were sufficient, except for nitrogen in the case of the oak and potassium and magnesium in the case of the beech. This finding runs through all other investigations, which have shown that the leaf nutrient contents from the dumping of forest gravels are sufficient.

If, on the other hand, the nutrient contents of the soils analyzed at the problem sites are considered, it becomes clear that in some cases a deficiency in the nutrients phosphorus and magnesium and in many areas also nitrogen occurred. With the other nutrients, the supply could not be called particularly good, but it could not in the end be held responsible for causing the harm. In the case of some soils it was also shown that the supply of calcium is inadequate and a strong acidification was found as far as into the aluminum buffer range.

FRIEDRICH has demonstrated a relationship between the nutrient conditions and the different proportions of loess in the forest gravel [408]. Thus, for the forest gravel group with ≥50 % loess and the soils with 25 – 33 % loess neutral to weakly acidic reactions are found. At unlimited exchange capacity calcium and magnesium almost exclusively make up the exchangeable cations. The reserve of phosphorus in the loess-rich forest gravels can also be regarded as high, but naturally in young forest gravels the proportions of carbon and nitrogen in the dry material are low. The forest gravels with 20 or even 10 % loess appear distinctly worse. The pH values of these gravels are in the acid range (Table 45).

Table 45. Chemical state of soils of forest gravel with varying proportions [406]

Surface profile no.	Proportion of loess, %	Depth, 10^{-1} m	pH ($CaCl_2$)	AK_E	%C/d.m.	%N/d.m.	C : N ratio	P, mg/100 g

AK_E = effective exchange capacity; d.m. = dry matter.

Especially in forest gravels with less than 10 % loess, aluminum and in some cases iron and hydrogen can have a high to predominant proportion of the cation exchange. The exchange capacities fall in each case by 30 % relative to the preceding soil groups (10 – 20 % loess, 25 – 33 % loess, etc.) that for forest gravels with small proportions of loess nutrient problems must occur.

In the bad forest gravels, possible heavymetals concentrations have been suggested as the cause of poor growth. Here, though, the analyses have shown that the heavy metals copper, silver, chromium, and zinc are present only in very small concentrations and thus cannot be the cause for the impairment of plant growth.

7.2.4.2. *Agricultural Recultivation*

DUMBECK has assembled the most important chemical parameters for initial soils in the Rhineland (see below).

Carbonate content	4.5 – 11.5 %
Nitrogen	total N = 0.02 – 0.05 %
Potassium	total K_2O = 300 – 700 mg/100 g soil
	calcium lactate soluble K_2O = 6 – 12 mg/100 g soil
Phosphorus	calcium lactate soluble P_2O_5 = 3 – 6 mg/100 g soil
Magnesium	$CaCl_2$ soluble Mg = 12 mg/100 g soil

Cation exchange capacity 8 – 10 mval/100 g soil

It is significant that, because of the admixture of carbonate-containing loesses, the initial pH values (7.5 – 8.0) are in the weakly alkaline range. The initial soils often show excellent nutrient supply. However, it can be observed in the course of recultivation when intermixing the soils that the nutrient contents in the recultivation substrata are decidedly low for agricultural use. Here, appropriately increased amounts of fertilizer are supplied, which exceed the uptake by plants and therefore lead to an enrichment in the soil. Since the humus contents are low, the nitrogen mineralization is also lower than on old sites. A 15 – 30 % nitrogen supply compensates the nitrogen release resulting from the lower mineralization.

Great problems have occurred in the recultivation of poor tertiary material, especially sands, in the mining districts of Central and former East Germany. The content of marcasite and pyrite led to an enrichment of the soil with acids, which can only be contained by extensive liming using power station ashes or lime fertilizers. Above all, the tertiary sands having a total sulfur content >2 % also must be viewed critically for improvement measures, since often with them only a superficial remediation is possible; and, with deep rooting of plant species, this can lead to considerable growth reductions.

In the discussion of improving agricultural or silvicultural use on poor substrata, the recycle of recycling substances also has been considered. It is being discussed above all in the case of recultivation, to what extent sewage sludge, wood chips, composts, and other recycling products can be used. The previous studies show that for difficult recultivation situations a distinct improvement can be seen, especially in the medium term.

7.2.5. *Soil Biology*

Soil is a basic compartment of terrestrial ecosystems (see also Chap. Function and Utilization of Soil). All nutrients are recycled in the soil through a cascade of smaller and smaller animals, fungi and bacteria. Many of the aspects of stability in ecosystems depend on the performance of these organisms. In the first stage the reclaimed substrates are colonised by airborn species: microorganisms, aeronautic spiders, flying insects, algae and plants with winddriven seeds. The further establishment of more demandig species without farreaching propagules or flight mechanisms depends much on the quality of soils. (For further discussion see [410].)

It has been demonstrated, that adverse chemical properties of the soil — especially acidic substrates — prevent soil dwelling earthworms from colonization [411]. An other effect is depending on the physical properties: compaction has proved to be the main factor impeding the development of a stable soil fauna. In compacted soils areation and percolation of water are reduced. The burrowing activity of the common earthworm (*Lumbricus terrestris*) is stopped at bulk densities above 1.6 g/cm^3 [412] and rooting of plants is impeded. Therefore, the careful selection of soil substrates and gentle dumping are most important for the establishment of a diverse and efficient soil fauna and flora.

On forest gravel in the Rhineland soil texture exerts a major effect on establishment of earthworm populations: higher contents of clay and silt favore soil dwelling species. If loess content of the forest gravel is at minimum 40 %, earthworm communities — compareable to those on undisturbed sites — are able to establish within ten years [413].

Colonization is much faster than suggested by studies on the dispersal of earthworms [414]. Therefore it is assumed, that at least cocoons or even living animals are translocated when topsoil is mixed in the soil substrates [415].

Land-use after substrate placement is crucial for the biological development. On afforested reclaimed stands with loess soil, total carbon reaches levels of more than 2 % at depth 0 – 10 cm and 0.8 % (depth: 10 – 30 cm) within 20 years, compared to about 0.4 % (depth: 0 – 30 cm) under agricultural use [416].

Recently, scientific studies focused on the ecological effect of the highly divers microrelief on unleveled reclaimed land. Preliminary observations suggest, that in the depressions of the rough surface organic material and fine soil is accumulated. Thus favoring hot spots of biological activity and facilitating the establishment of species that need a moist environment, rich in biomass.

8. Legal Aspects of Soil Protection

Peter-Christoph Storm

8.1. Foundations of Soil Protection Law

8.1.1. *Land Law*

Following Roman legal tradition, the open air and flowing water are not things in possession in the legal sense and not accessible to action under (private) law. In contrast, the partition of the land, is considered an original law of the earth. The taking of land is regulated by land law: this allocates the land to persons in law as bearers of rights and duties and governs legal relationships with regard to the land. It is expected that the user of the land will also protect, maintain, and preserve it. Until recently the land has been regarded not only as immovable and nonincreasable but also as indestructible. Since the 1970s, however, concern about human's natural fundamental requirements of life has developed on the one hand from the recognition that natural resources are limited, and on the other from a growing awareness both of the increasing anthropogenic pollution (or other harmful change of the natural condition) of soil, water, and air and of their dwindling renewability. The protection and maintenance of human's natural fundamental requirements of life, i.e., care of the environment, has developed into a public task for public benefit going far beyond the interests of the individual for private benefit protected by neighbor law. Within the framework of care of the environment, care of the soil has been added as a new terrestrial primary law. The soil is no longer indestructible. The supposed identity of interests between soil use and soil care appears no longer adequate to maintain the soil as a part of the natural fundamental requirements of life for present and future generations.

8.1.2. *Soil Protection Law*

Land law is therefore supplemented by a soil care law or soil protection law [417-420], that

1. as a collective concept gathers together the legal provisions that serve the protection, maintenance, and development of the soil,
2. can be described as a legal system of measures for intervention, incentives, and planning for the realization of certain soil-protection goals, including the necessary processes, organization and sanctions — and therefore as a part of environmental law, and
3. as a result of its primary purpose of protection, differs from regulations for land use in the narrow sense, without it being possible to avoid the overlapping of the two spheres in the face of the subject of regulation named.

8.2. Foundations of Soil Protection Policy

8.2.1. *Soil Protection in Germany*

The environmental program of the government of the Federal Republic of Germany of 1971 [421] already designated the soil in its “triad of goals” as an environmental medium, alongside water and air, that had to be protected from harmful human actions. The soil protection concept of the German Federal Government of 1985 [422] described soil protection as a cross-sectional task of environmental protection and emphasized two central approaches for enhanced soil protection:

1. Minimization of the qualitatively or quantitatively problematic entry of substances and
2. A “trend reversal” in land use [423]

8.2.2. *International Soil Protection*

Already in 1972 in the regional framework of the Council of Europe a “European Soil Charter”, which formulates a Europe-wide soil protection policy in twelve articles, was adopted as a recommendation for the Member States [424].

In 1981, the protection of the soil was recognized worldwide as a problem in environmental law by the Montevideo Environmental Law Program of the United Nations [425]. The program describes as goals of the legal measures in the soil protection subsection at national, regional and global levels

1. To prevent the impairment as a result of human actions of the sustained productivity of the soil, resulting in erosion, desertification, salination, deforestation, overuse, contamination, or excessive land use, and
2. If the need arises, to remediate polluted soils

Aside from the application of appropriate worldwide basic principles, guidelines, and recommendations at all levels of control (“World Soil Charter”, “World Charter for Nature”), a stronger emphasis on soil protection in the laws at national level is encouraged.

The Conference of the United Nations for Environment and Development of 1992 in Rio de Janeiro worked out in the action program “Agenda 21” among other things instructions for an integrated approach to the planning and management of land resources (Chap. 10 of the Agenda) and the combating of desertification (Chap. 12 of the Agenda), which need national enforcement [426]. In the following sections the soil protection law in Germany is described as an example.

8.3. Constitutional Soil Protection

Soil protection is part of the national task of care of the environment, even if this national task was not expressly enshrined in the German “Grundgesetz” until 1994 (Art. 20a GG) . With regard to intervention measures, soil protection experiences constitutional barriers. The measures must be suitable, necessary, and proportionate.

The soil protection legislator has correctly to value the realities underlying his decisions, to which end scientifically based data are drawn upon, especially for the definition of soil-protecting environmental standards (soil values) to quantify soil damage. This does not exclude precautionary measures if there is not (yet) sufficient scientific knowledge. In addition the remaining constitutional standards of competence and of guaranty have to be observed, above all the warranty of property under the Grundgesetz (Art. 14 Grundgesetz). The social obligation of land ownership is of increased importance because of the nonincreasability of the land. Where constitutions of the German “Bundesländer” (federal states) contain state objectives in favor of care of the environment, these also include soil protection within the scope of the federal state's spheres of jurisdiction.

8.4. Soil Protection under Administrative Law

The protection of the soil is found in a large number of legal regulations from all stages of legislation, supplemented since March 1999 by the Federal Soil Protection Act (Bundesbodenschutzgesetz – BBodSchG) and since July 1999 by the Federal Ordinance on Soil Protection and Contaminated Sites (Bundes-Bodenschutz- und Altlastenverordnung – BBodSchV) [429] . Where a federal state has its own soil protection law, this is applied, provided regulations under federal or state law do not contain provisions to the same effect or to the contrary [427].

The soil protection standards are mainly administrative law. Environmental private law (e.g., environmental liability, Umwelthaftungsgesetz) and environmental criminal law, on the other hand play only a supporting role in soil protection owing to their essentially sanctioning character. Soil protection law is accordingly principally administrative law and as such a part of environmental administrative law, which in turn is part of special administrative law. If no special regulations exist under the law of a particular federal state, soil protection follows the provisions of the remaining environmental administrative law.

8.5. Soil Protection Goals

8.5.1. *Soil*

The meaning of the term soil has in each case to be obtained from the context of legal rules in which it is used; the regulatory purpose of the rules can circumscribe the connotation. However, as a starting point for a legal description of the soil as a value to be protected it can be defined as the topmost layer of the earth's surface, inhabited by animals, plants, and microorganisms, on the firm ground and below the water surface of waters above ground. Beyond that, the protected zone of standards significant for the soil can also cover the uninhabited underground, as far as it is accessible to anthropogenic influences. The new federal act on soil protection [429] defines the soil as the topmost layer of the earth's surface, as far it is bearing soil functions (see Section Protection of Soil Functions), including the fluid or gaseous parts of the soil, but excluding the groundwater and the ground below the surface of water.

8.5.2. *Protection of Soil Functions*

The soil is protected legally as a part of hu-man's fundamental requirements of life for the sake of its functions, especially as a habitat for biomass, as a filter, as a stock of raw materials, and as building land. The legal protection has to guarantee that the soil can provide its varied functions in the required quality and quantity for a long time. The reference to the soil as part of the natural fundamental requirements of life shows the ecological approach to soil protection, which not only views the soil sectorally and as a medium comparable with the environmental media water and air, but also sees it together with these media and the sunlight as the basis of all life [428]. Futhermore the reference makes clear that soil protection is not an end in itself, but rather, like care of the environment as a whole, in the end always occurs for human's sake.

8.5.3. *Impairments of the Soil*

The protection of the soil is directed against impairments of the soil quality and quantity that are caused in the soil by material and nonmaterial anthropogenic intrusions in the soil.

Material intrusions in the soil can be brought about by the directly or indirectly caused entry of substances (soil change by substance entry). Soil impairment by substance entry means the effects of chemical elements or chemical compounds that are capable of detrimentally changing the natural condition of the soil.

Nonmaterial intrusions in the soil include intrusions through an alteration of the soil's use, whereby the efficiency of the soil or of the ecosystem or of the landscape can be impaired considerably or for a long time (soil consumption). In addition they include other non-material intrusions into the soil, which, without being soil consumption in the sense just named, can bring about corresponding impairments.

8.5.4. *Soil Protection by Provision and Aftercare*

Protection of the soil signifies not only the warding-off of impairments of the soil. Protection of the soil also comprises maintenance and development in the sense of shaping, improvement and restoration (remediation of contaminated sites) and provision that impairments do no occur at all and that the soil can perform its diverse functions for a long time. Soil protection accordingly means both precautionary care and aftercare.

8.5.5. *Direct and Indirect Soil Protection*

Soil protection can occur directly as the main or subsidiary goal of regulation, if the soil is identified explicitly as the value to be protected. Direct soil protection can also be spoken of when the legal system uses terms such as environment, natural fundamental requirements of life, natural resources, ecosystem, or nature and landscape, because these notions include the soil as protected property. Soil protection can also occur indirectly, however, by other goods and values being protected, the soil being co-protected without itself expressly being protected property.

8.5.6. *Relative and Absolute Soil Protection*

In view of the variety of the soil's functions and of the multitude of demands that are made upon it, the legal system has to provide for an appropriate solution of possible conflicts of goal. When weighing different interests, consideration is accorded to soil protection (relative soil protection). Soil protection can also be given priority, either generally or in the individual case (absolute soil protection), for instance, by regulations on sewage sludge application.

8.6. Soil Protection Measures

8.6.1. *Types of Measure*

The set of instruments under administrative law, consisting of soil protection measures for intervention, incentives, and planning (triad of measures) is used to realize soil protection goals. The measures interfering with the legal rights of the individual are orders and prohibitions or restrictions directed to the carrying out, toleration, or neglect of particular actions. They are supplemented by instruments that, by means of specific incentives such as the grant of tax allowances or of user advantages, indirectly guide human behavior to the realization of goals serving soil protection. With the aid of the incentive measures the environmental administration influences corporate behavior. This involves the erection and maintenance of supply and waste-disposal equipment, public consultation and information, the public financial support of activities appropriate to soil protection, and public compensation. Within the triad of measures the measures of environmental planning have a special function, because they above all are capable of realizing the precautionary principle.

The measures can be restricted spatially to certain areas (protected areas). They can distinguish chronologically between old soil contaminated sites and new soil impairments.

8.6.2. *Classification of Soil Protection Measures*

The standards significant for soil protection can be classified according to the type of soil intrusion into protective standards against impairments that are brought about by material intrusions and those that are brought about by nonmaterial intrusions.

8.6.3. *Measures against Material Soil Impairments*

The soil receives direct or indirect protection as a result of environmental law from impairment(s) of the soil brought about by directly or indirectly caused entry of substances in the environmental care areas of the protection of soil (Bundes-Bodenschutzgesetz), of waters (Wasserhaushaltsgesetz, Water Resources Policy Act), avoidance and disposal of wastes (Abfallgesetz, Federal Waste Act), emmission protection (air pollution control; Bundesimmissionsschutzgesetz, Benzinbleigesetz, etc.), radiation protection (Atomgesetz, Atomic Act), protection from harmful materials (ChemG) and genetically engineered organisms (Gentechnikgesetz, Genetic Engineering Act), and nature conservation (nature protection and landscape preservation, soil protection; Bundesnaturschutzgesetz). These are supplemented by the Building Regulations Law (Landesbauordnungen) and the General Police and Regulatory Law (Landespolizeigesetze) but also by the Regional Planning Law and Federal Planning Laws (Raumordnungsgesetz, Landesplanungsgesetze) so far as this can control entries of substances by appropriate allocation of soil uses. The main emphasis of the regulations that are intended to protect the soil from the direct entry of substances is in protection from harmful substances and organisms modified by gene technology, avoidance and disposal of wastes, and protection of waters. The immission protection regulations, in particular, give protection from the entry of substances via the air path by measures that operate at the source of emissions. In the area of general environmental care, the environmental impact assessment prescribes for particular projects the determination, description, and evaluation of their effects, also on the soil, and requires consideration of the result of the evaluation during the licensing of the project.

8.6.4. *Measures against Nonmaterial Soil Impairments*

Standards governing nonmaterial soil impairments are stipulated in laws of nature protection and landscape preservation, and of soil protection (Bundesnaturschutzgesetz, Bundeswaldgesetz, Bundes- und Landesbodenschutzgesetze). This core area is supplemented by the standards controlling soil protection of environmental planning and regional planning (Raumordnungsgesetz, Landesplanungsgesetz), of zoning (Baugesetzbuch), and of individual technical plans. For projects subject to an environmental impact assessment the observance of soil protection is assured. This is supplemented by direct and indirect soil-protection standards of agricultural law (e.g., land consolidation, Flurbereinigungsgesetz) and of the Federal Mining Law (Bundesberggesetz).

8.7. Development Trends

8.7.1. *Further Development of German Soil Protection Law since 1985*

At first sight, the soil protection law in force in Germany has an appearance of strong fragmentation. But this alone must not lead to the conclusion that the soil is unprotected or only very incompletely protected. The legal translation of the ecopolitical demands for a reduction of the direct and indirect entry of substances into the soil and for a reduction of soil consumption certainly signals weaknesses of standardization of the law in force. But this is up to now combated less by a special soil protection law than by a strict application of the soil protection law in force and its development.

8.7.2. *The German Soil Protection Act 1998*

The German Soil Protection Act 1998 came into force on 1 March 1999 [429]. It contains in its Article 1 an “Act for the Protection from Harmful Changes to the Soil and for the Remediation of Contaminated Sites (Bundes-Bodenschutzgesetz, BBodSchG)”; Articles 2 to 3 contain amendments to pertinent environmental laws to ensure the dovetailing of the soil protection law with the remaining environmental law.

The Federal Soil Protection Act aims to protect the soil from harmful changes and to make provisions against the build-up of harmful soil changes. Aside from its precautionary function, comprising the defense against hazards and the reduction of detrimental effects on the soil, the law also stipulates soil protection by aftercare for the removal of harmful soil changes and contaminated sites.

The purpose of the Act is highlighted by two principles, which present soil protection as soil function protection:

1. Preservation or restoration of the natural functions of the soil as a fundamental requirement of life and as living space for humans, animals, plants, and soil organisms, as part of the ecosystem, as a degradation, equilibration, and synthesis medium for substances based on its filtering, buffering, and matter conversion properties
2. Preservation or restoration of the soil in its functions as a raw material deposit, as a site for agricultural and silvicultural use, as an area for settlement and recreation, as a site for economic uses, traffic, supply, and waste disposal as well as an archive of natural history and the history of civilization

The Act defines *harmful soil changes* as changes of the physical, chemical, or biological condition of the soil that, depending on their nature, extent, or duration, are capable of impairing the soil functions and thereby of bringing about dangers, considerable disadvantages, or considerable nuisances for the individual or the general public. Here the ecological functions of the soil are included as protected property of the general public. The law also takes into account whether the possibility of a sustained impairment of the natural functions of the soil exist which cannot be reconciled with the protective and user interests of the individual or with the common good.

Obligations to provide against harmful soil changes, for accident prevention, and for the elimination of harmful soil changes support the objective of the law. Special regulations are made for the registration and remediation of contaminated sites. The obligation of remediation of contaminated sites is put in concrete form by rules and orders on soil-dependent pollution limits and test values as well as requirements for removal of pollutants. The federal states can also prepare soil protection plans for the remediation of areas in which harmful soil changes occur, or are to be expected.

8.7.3. *Soil Protection in the Draft of an Environmental Code (UGB)*

The German federal government wants to create an Environmental Code (Umweltgesetzbuch – UGB) that brings together, unifies, harmonizes, develops and updates the environmental law, which is constituted by more than 20 special environmental acts; a draft has been prepared by an independent expert commission in 1997 [430]. In the specific part of this draft of an Environmental Code, chapter ten will regulate soil conservation (Art. 326–354) on the basis of the Federal Soil Protection Act.

1. Introduction

As mankind eventually adopted a more settled, non-nomadic way of life, people became increasingly involved in the technical aspects of

Figure 1. The increasing worldwide demand for water, projected into the future

water. To a large extent, the primary concerns in the beginning were utilization and improvement of existing water resources, together with protection against the hazards and potential harm associated with uncontrolled natural water. It was only toward the end of the nineteenth century that wastewater became an issue in science, technology, and legislation: specifically, its production and treatment, in terms of both municipal and industrial sources [1], [2].

As early as 4500 years ago the first prerequisites were met for urban and agricultural water management. This occurred in the Indus Valley, and it encompassed irrigation and drainage systems, canals, and sewage facilities. Even so, the treatment of wastewater in formal waste-treatment plants by means of the microbial degradation of wastewater components was reported for the first time in 1892 in London, followed in 1895 by similar efforts in Frankfurt/Main. In both cases it was municipal wastewater, including that from artisans, craftsmen, and small factories, typical of larger cities of that time. Already in the Middle Ages communal wastewater from Milan was being used directly to irrigate the meadows along the outskirts of town. Much earlier, in Greco – Roman times, extensive facilities were erected and maintained for supplying drinking water to cities. Wastewater in those days presented no major problems, and sewage systems were regarded less as a means of collecting water for reuse than as a way of draining off potential sources of hazard and preventing pollution of the streets, with the attendant risk of a spread of vermin and epidemics.

Development of the organized utilization of water as an essential resource for human beings, animals, and plants led to further technical strides, such as dams against flooding or for storage purposes, waterways designed for transport, and harbors on the seacoast and along inland waterways. Problems of wastewater arose gradually during the same period in conjunction with the increase in urban population as the natural self-purification capacity of surface waters proved no longer able to keep pace with development. Risks related to groundwater contamination are associated not only with emissions in the form of wastewater; the ground – air cycle plays a role as well via atmospheric deposition [3]. The state of a particular body of water can be described by a set of code numbers, but the core of the problem is in fact a sum of all the processes leading to the observed state. In this case, the essential element is the kinetics of two opposing processes: the rate of pollution, and the rate of cleansing. Each of these is in turn a combination of natural and anthropogenic phenomena applicable to the site in question. Most of the problems are derived not from absolute numbers, but rather from population densities, production densities, productivities, etc., in the various urban centers of the industrialized world, all of which actually have access to an adequate supply of natural water.

Utilization of water power generated by falls, tides, or waves, and then transformed into the power of mills, pumping plants, and turbines,

has been responsible for very little of the wastewater problem, which in the early days of industrialization was due largely to hammer and stamping mills in the metalworking industry and various ore-dressing facilities. Only when the use of water led to its exploitation as a production medium the greatest specific wastewater load was reached. This was especially the case with process wastewater derived from tanneries and dye works. To this day, street names associated with these activities can be found along inner-city watercourses in the old city centers of such medieval towns as Nuremberg and Strasbourg.

High densities of population and industry – as in the Ruhr area of Germany during the nineteenth century – necessitated the development of a complex water economy. Thus, the Ruhr – Emscher water system provided simultaneously for drinking water, industrial water, and inland waterways, and it even included a wastewater disposition system fully consistent with the knowledge and technological potential available at that time.

In the terminology of water economics, *consumption* of water refers to a loss of quantity, not a decrease in quality. In this sense, consumption represents that part of the water supply that is lost in the course of use, primarily through evaporation. This fraction of the water is permanently withdrawn – at least from the local water cycles – and is thus no longer available for further utilization, so it must be replenished with water from precipitation, springs, or wells [2], [3].

As industrialization proceeded, two unique characteristics of water acquired rapidly increasing importance: its high specific heat capacity, and its rather high solvent power with respect to many inorganic and some organic substances. The consequences of these factors in the context of the production and disposal of wastewater are quite different, however. Water that is intended to serve as a heat reservoir, cooling agent, steam source, etc., must be cleaned before use in order to prevent corrosion and erosion in turbines and heat exchangers, and it is subsequently returned to the environment in a purified state, albeit at a higher temperature. On the other hand, water in its function as a reaction medium, or even a reaction partner, has now developed into the most significant source of wastewater in industry. Entire branches of manufacturing are based on production processes carried out in the aqueous phase, where water is used as a solvent, dispersing agent, transport medium, and reagent. This is perhaps most evident in the case of breweries, in sugar, paper, and pulp factories, in dye manufacture by chemical concerns, and in dye works, tanneries, and the like where the real problem is one not only of the actual content of the wastewater, but also its quantity [1], [4].

For the year 2000, a global balance of quantities and fluxes shows an overall water supply of 25 000 km^3 and a water demand of 6000 km^3, representing 24 % of the directly usable supply [1]. When this is allocated among the major consumers and account is taken of the corresponding levels of specific water consumption (as defined above; i.e., evaporation), several trends with regard to quantities and types of waste water are discernible:

Consumption category	Percentage of total demand (6000 km^3)	Consumption (evaporation) as a percentage of demand
Domestic	8	20 – 30
Industry	29	15 – 20
Agriculture	59	75
Storage losses	4	100

Water circulation through the atmosphere occurs relatively rapidly. The atmosphere contains 13 000 km^3 (ca. 0.02 %) of the overall (liquid) global water reserve of 1.3×10^9 km^3. The annual quantity subject to evaporation (which is equal to the annual amount of precipitation) is estimated at 475 000 km^3. This corresponds to a 35-fold annual turnover of the atmospheric content, which means water exchange between the atmosphere and the surface of the earth is complete every 9.5 days. In some cases local circumstances lead to considerable deviations from these global values.

Wastewater treatment becomes especially important in times of water scarcity. This is particularly true when agriculture, domestic water needs, and industry find themselves in vigorous competition. The greatest increase by far (Fig. 1) is anticipated for agriculture [1], assuming for the year 2000 a world population of $6 - 6.5 \times 10^9$.

Water is regarded as the chief raw-material problem of the future, elevating wastewater treatment to the status of a recycling technology. This involves "substance protection" in the sense of sustainable development (→ Sustainability

and Industrial Chemistry – Ethical Aspects and Approaches), together with the maintenance of an adequate supply of drinking water, an emphasis that goes beyond the earlier concern directed almost exclusively toward environmental protection, especially the protection of natural waters.

Each of the processes described below has its place in the broad spectrum of technical possibilities. The question of what is the "best process" should thus be replaced by a search for the most suitable process in a particular circumstance, taking fully into account the nature of certain definable problem cases. Modern technological development of wastewater treatment has occurred largely in and with the aid of the chemical industry. However, the wastewater problem and its treatment is of interest not only to this particular aspect of industrialized society. Numerous other branches are affected as well, especially municipalities, often to an even greater extent.

There is no shortage today of diverse international experience in the construction and operation of waste-treatment plants. In fact, in some places this has developed into its own separate branch of process engineering. It is still worth noting with respect to terminology, however, that some of the reasoning applied to wastewater concepts and standards of evaluation has been borrowed from neighboring disciplines, especially limnology and biology.

2. Biological Wastewater Treatment

Large waste-treatment plants intended for the purification of industrial or municipal wastewater utilize a combination of processing techniques:

1) *Chemical treatment* – insofar as necessary – for the neutralization and precipitation of wastewater components
2) *Mechanical treatment* for the elimination of undissolved substances, including screening, clarification, and filtration
3) *Biological treatment* for the removal of dissolved substances, in the course of which colloidally dispersed materials are also destabilized and flocculated; substances can also be eliminated by adsorption onto the biomass

Biological wastewater treatment involves the biotechnological application of processes that occur in nature as well, albeit very slowly. These are the processes known broadly as the "selfpurification of surface water."

In the presence of dissolved oxygen (DO), biological metabolism on the part of certain microorganisms always found in a body of water proceeds in an *aerobic* fashion. In this process, organic wastewater components may be oxidized all the way to carbon dioxide (*mineralization*) or some other metabolic product, whereas ammonium ion is transformed into nitrate (*nitrification*). In the case of excessive contamination with oxidizable substances, all available dissolved oxygen ultimately becomes consumed. Replenishment of the oxygen supply by diffusion through the air – water interface is limited, for which reason aerobic metabolism slowly ceases, and a change occurs via the *anoxic* state to *anaerobic* metabolism. Under anoxic conditions, oxygen required for aerobic metabolism is acquired through the biological reduction of some oxygen donor (e.g., nitrate to nitrogen, known as *denitrification*, or sulfate to hydrogen sulfide). Purely anaerobic metabolism is limited primarily to sediments at the bottom of a natural body of water. Here organic substances are first converted to carboxylic acids (*acidification* step) and then disproportionated to carbonic acid, methane, and hydrogen (*methanogenic fermentation*).

Targeted biological wastewater treatment takes advantage of all three types of metabolic process: aerobic, anoxic, and anaerobic. The choice of a particular process or perhaps a combination of processes depends on the quality of the wastewater in question and the goal of the treatment. The advantage of biological wastewater treatment is the enormous adaptability of microorganisms to a wide variety of nutrient media. Such adaptation to different wastewater components and wastewater qualities may occur very rapidly or it may require longer periods of time. During adaptation, metabolism is altered through the synthesis of new enzymes or exoenzymes, or else new metabolic pathways may become available. Successful adaptations are often coded into *plasmids* (see Section 2.1.1.1), which are relatively small DNA units not permanently integrated into the bacte-

rial genome. This metabolic activity, which frequently provides a competitive advantage, can be transferred to other microorganisms by *plasmid transfer*. Since adapted microorganisms are able to metabolize the available substrates more effectively and more rapidly, they also produce more cell substance and undergo multiplication by cell division. Due to plasmid transfer and rapid growth of the microorganisms, biological systems exhibit a high degree of adaptability, even to greatly fluctuating wastewater compositions.

Since anaerobic wastewater treatment has an efficiency <85 % [5], [6], it is essentially used only for pretreating wastewater characterized by a high organic load (>5000 mg/L) and, insofar as possible, a constant quality (e.g., that from the production of citric acid, yeast, alcohol, sauerkraut, sugar, paper, or pulp). It offers the advantages of low energy consumption, production of an energy-rich sewage gas that may be amenable to further use after some preparation, and relatively little clarification sludge that must be subjected to subsequent treatment (see Section 2.1.2). On the other hand, this same low rate of sludge accumulation is responsible for the high sensitivity of anaerobic systems to toxic components of the inflowing wastewater, and for increased discharge of microorganisms (see the discussion of bacterial retention in Section 2.1.2).

Aerobic wastewater treatment generally represents the last biological step. It offers the advantage of a high rate of sludge growth that not only facilitates handling the various components of inflowing toxic wastewater but also provides an efficiency > 85 %. The disadvantages are high energy consumption in supplying oxygen to the microorganisms and the production of considerable clarification sludge (see Section 2.1.2). Table 1 provides a comparison of the two processes.

Processes that might be described as "close to nature" were important in the early stages of the development of biological wastewater treatment [7]. These include landbased treatment (spray distribution, irrigation, infiltration fields), use of aerated and nonaerated wastewater ponds [8], and fish ponds. Although these never played a significant role in the treatment of wastewater from the chemical industry, they have been used for municipal sewage and the wastewater from sugar factories and facilities processing animal cadavers. Today such processes are rarely applied, because they give rise to such insoluble problems as hygienic concerns, nuisance due to flies, and unpleasant odors – a result of the anaerobic conditions encountered at least part of the time. Nevertheless, wastewater ponds have experienced something of a renaissance as "polishing ponds" [9], especially in the area of municipal wastewater treatment. Processes of a more technical nature were developed in the late 19th and early 20th centuries, primarily in England. These include intermittently submerged reactors, the trickling-filter process, and the activated-sludge process (see Section 2.1.2).

The method of choice in the chemical industry today is the activated-sludge process, occasionally replaced by the trickling filter in individual cases (see Section 2.1.4).

In the interest of solving specific problems, the process-engineering aspects of the activated-sludge process have been optimized and incorporated into closed systems as a way of avoiding the potential emission of odors [10]. These special processes utilize deep water columns in order to minimize the off-gas volume, taking advantage of the increased solubility and uptake of oxygen under pressure. They include biotowers (Turmbiologie, Hochbioreaktor) and deep-shaft systems, as described in Section 2.1.3.

Prerequisites for the successful implementation of biological wastewater treatment are a system-dependent microbial degradability of the wastewater components and the absence of effective concentrations of substances that would inhibit degradation. These considerations apply to all aspects of the wastewater regime.

In the chemical industry, economic factors usually dictate the inclusion of a wastewater-separation system. Thus, wastewater that is not in need of treatment (*clean water*), especially cooling water, is separated from that which does require treatment. Clean water can be discharged directly into the receiving stream. If the wastewater requiring treatment fails to meet the quality specifications for biological waste treatment it must first be subjected to decentralized chemicophysical pretreatment, after which it can be fed into the central waste-treatment plant for purification [7], [11] (Fig. 2).

Specific wastewater loads can be reduced or even avoided through measures of the type

Table 1. Advantages, disadvantages, and specific process parameters associated with anaerobic, anoxic, and aerobic biology

Parameter	Anaerobic	Anoxic	Aerobic
DO (mg O_2/L)	0	0	>0
Energy consumption	low	low	high
Sludge accumulation	low	high	high
Sensitivity to toxic substances	high	low	low
Removal efficiency (COD)	<85 %	varies depending upon denitrification	>85 %
Removal efficiency for nitrogen	0	45 – 90 % (nitrification required)	0
Suitable as pretreatment	yes	yes	yes
Suitable as last stage	no	no	yes

Figure 2. Decentralized and centralized aspects of wastewater treatment

recommended in conjunction with process-integrated environmental protection [7], [11], [12].

The entire wastewater regimen is also reflected in the approach taken to wastewater decision making. For each type of wastewater, all the following questions must be rigorously addressed to ensure consistent and safe disposal (see Fig. 3):

1) Can the amount and contamination level of the wastewater be reduced or even eliminated by process-integrated means?
2) Does all the wastewater in question in fact require treatment (i.e., would a separation system be useful)?
3) Is the wastewater suitable in its present form for biological treatment, or should it be subjected to decentralized pretreatment?

These considerations apply equally with respect to both direct discharge (for companies that have their own central wastewater-treatment plants) and indirect discharge (for companies that dispose of their wastewater via a public wastewater facility).

2.1. Aerobic Treatment

In the self-purification of any body of water, oxidative metabolic processes tend to be very slow:

Figure 3. Decision diagram dealing with wastewater formation, avoidance, separation, and treatment

on one hand because the concentration of nutrients is low, but also because almost no optimization of the process engineering is possible apart from aeration of the water.

Figure 4. Aerobic metabolism

In processes, such as these, heterotrophic organisms oxidize organic substances to CO_2 or some other metabolic product, thereby utilizing organic materials as a carbon source for creating new cell substance, with rapid multiplication by cell division (Fig. 4). Meanwhile, autotrophic organisms oxidize ammonium ion (NH_4^+) to nitrate (NO_3^-), where cell substance must be derived from CO_2 as the carbon source, resulting in slow multiplication by cell division.

The biotechnological application of this self-purification scheme requires optimization of the process engineering in such a way as to attain the highest possible space – time yield with adequate efficiency. A few of the relevant factors are as follows:

1) The concentration of nutrients in the wastewater should not be too low. This particular requirement can normally be met.
2) As many suitable organisms as possible should be present within the bulk (bacterial retention) to ensure stable biocenosis (mixed culture; see Section 2.1.1.2).

3) The bacteria must be provided with an adequate supply of oxygen to support aerobic metabolism (aeration).
4) The three reaction partners – bacteria, substrate, and dissolved oxygen – must be brought together in a targeted way.
5) The growth rates for the different bacteria must be well matched (sludge age).
6) The optimal environmental conditions (pH, temperature) for biological degradation must be established.
7) The C: N: P ratio required for the growth of cell substance must be assured [13], and all required trace elements must be present.

Figure 5. Relative size and shape of various viruses [17]

2.1.1. Biological Principles

Broadly speaking, only chemical reactions or physical separation processes lend themselves to the elimination of unwanted wastewater components. Living creatures, especially microorganisms, have developed a tremendous potential for chemical reactivity over the course of time (see Section 2.1.1.1). Their cells in fact constitute tiny "bio"chemical reactors. Aerobic, heterotrophic organisms oxidize organic compounds with the aid of oxygen. Moreover, the microorganisms themselves represent natural sorbents that bind both organic substances and heavy metals. The flocs, threads, and films formed by the aggregation and intergrowth of these organisms behave like small particle filters that clarify the wastewater mechanically. Associations of this type (*biocenoses*, see Section 2.1.1.2) can be established in many kinds of reactors – activated-sludge stages, trickling filters, intermittently submerged reactors, waste ponds – to assist in wastewater treatment. The conversions leading to actual degradation of unwanted wastewater components constitute integral parts of the phenomenon of biological metabolism (Section 2.1.1.3).

2.1.1.1. Organisms

Organisms can be regarded as unicellular or multicellular compartments that are separated from the environment, have their own metabolism, and are capable of growth and potentially of multiplication. Derived from the Greek word *organon* (tool, instrument, organ) via the Late Latin word *organicus* (well-ordered) the designation "organism" indicates that despite their apparently trivial accomplishments, such creatures have developed complicated, closely regulated systems for performing their tasks, and also that they act on one another and on their environment in a complex manner [14].

As a rule, organisms involved in biological wastewater treatment are invisible to the naked eye. Depending upon their structures and cellular components they can be subdivided into bacteria, fungi, plants, and animals, with viruses representing a special group of their own.

Viruses. The term "virus" is borrowed from Latin, and means "poison." Viruses lack an independent metabolism, and are unable to grow and multiply on their own. Viruses are not organisms; they are only modified, independent building blocks derived from organisms [15], [16]. Since viruses do not have their own metabolism

they are necessarily intracellular parasites, dependent upon true living organisms for their replication. A distinction is made between deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) viruses depending on the nature of the carrier of genetic information. The corresponding DNA or RNA is associated with proteins (the *core*) packed in a shell (*capsid*) of mostly uniformly arranged proteins (*capsomeres*), which may in turn be surrounded by another shell (the *envelope*). Most viruses are polyhedral, tubular, or bag-shaped. Some bacteria-destroying bacteriophages display a rocket-shaped projection in addition to a polyhedral capsid (Fig. 5) [17].

Viruses are found in all municipal wastewaters, and they represent a serious problem, especially with respect to hygiene. Tiny pathogens with lengths of up to 2 µm or diameters of up to 200 nm, pass through bacterial filters, and are separable by sedimentation or flotation only when aggregated or bound to other particles [18]. Viruses or their fragments are detectable in treated and untreated wastewaters [19–21], including infectious doses of the pathogenic viruses responsible for poliomyelitis, hepatitis, and gastroenteritis. However, viruses are partially eliminated [22] during wastewater treatment, and they are destroyed by enzymes such as proteinases and nucleases that are formed by bacteria, algae, and other organisms ubiquitously present in the environment. Moreover, their sensitivity to UV light [22] and to photochemically formed reactants is well known [18].

Bacteria. The term bacteria, derived from the Greek word *bakterion* (little rod), refers to a series of very diverse unicellular microorganisms possessing no true cell nucleus; for this reason they are also called *prokaryotes* (after the Greek word *karyon*: nut, kernel) [14–16], [21].

Structure and Morphology [23], [24]. Only in exceptional cases do bacteria exceed a length of 10 µm. Under the light microscope, one can recognize spherical cocci, straight short rods or bent "vibrions," corkscrew-shaped spirilla, rootlike and amoeboid forms, etc. Bacteria also occur in pairs (e.g., diplococci), in fours, in threads, in nets, or in clumps, all encompassed by a common slimy shell. Although actinomycetes form mycelia and myxobacteria form fruiting bodies, cell differentiation is at most quite limited. The so-called wastewater fungus, *Sphaerotilus natans*, a chlamydobacterium, covers all nutrient-rich substrates with mycelia. Actinomycetes mycelia are undesirable in wastewater-treatment facilities because of sludge bulking [25], [26].

The bacterial cell [21] is contained within a cytoplasmic membrane, usually enclosed in a cell wall, that may in turn be surrounded by a capsule or a slime layer. The cell walls of most bacteria consist of a single-layer or multilayer murein sack to which teichoic acids or lipoproteins and lipopolysaccharides are attached. Bacteria with only one or a few murein layers lose stain most readily in Gram's method of staining, and are thus described as "gram-negative." By contrast, bacteria with many murein layers retain their stain (gram-positive). The capsule or slime layer is usually made up of polysaccharides and proteins, and in the case of *Salmonella*, for example, it causes virulence, resistance to bacteriophages, and resistance to drying. The lactic acid bacterium *Leuconostoc mesenteroides* leads to slime formation, especially in wastewater from sugar factories. At the same time, however, slime is what holds together the activated sludge floc, which always involves several types of bacteria [25].

Many bacteria possess one or more *flagella*, which serve as their means of locomotion. Velocities per second of up to 50 times the bacterial body length have been observed. Some bacteria are adapted to sliding on suitable surfaces.

Substances dissolved within the bacterial cell generate an osmotic pressure corresponding to that of a 10 – 20 % sucrose solution. If a stable cell-wall skeleton fails to form (e.g., due to penicillins), or is destroyed (e.g., by lysozyme), or if the internal pressure is increased by heating, the cellular contents escape, resulting in death of the bacterium.

In comparison with the cells of fungi, plants, and animals (eukaryotes), the bacterial cell itself shows little compartmentalization. Organelles like mitochondria, chloroplasts, the Golgi apparatus, and the endoplasmic reticulum are absent entirely, and bacterial ribosomes are smaller than those in eukaryotes [16]. Much of the cell is often filled with invaginations of the cytoplasmic membrane (for photosynthesis), gas vacuoles, or storage substances.

The well-ordered genetic material lies in the nuclear region of the cytoplasm, the *nucleo-*

plasm. There is no nuclear membrane, so bacteria lack a true cell nucleus. The DNA that serves as the genetic material (genome) forms a ring-shaped closed thread, typically with a contour length of up to 3 mm, the native state of which is called the bacterial chromosome. Smaller circular DNA fragments called plasmids are also frequently found in the cell [21]. These may become integrated into the bacterial chromosome – sometimes to be eliminated once again, occasionally taking genome fragments with them in the process (excision) [16], [23], [27], [28]. Although the information stored in plasmids is usually not essential for basic metabolism, it is of great significance with respect to resistances, stress tolerance, and vitamin and nutrient requirements (auxotrophs), as well as for the biological degradation of wastewater components.

Multiplication [16]. Bacteria usually multiply by fission, less frequently by budding. Depending on the species or strain, ten minutes to several hours are required for bacterial division under favorable conditions. The shorter the time between one division and the next (*generation time*), the faster the bacteria fill their habitat, and the better the activated-sludge formation.

If the conditions for life become very unfavorable, many types of bacteria form spores. These can survive extreme environmental conditions, but they make no contribution to material degradation in the wastewater-treatment plant. To assure optimal degradation potentials and to avoid unwanted losses, wastewater with a fluctuating composition should always be tempered.

Composition. The water content of the bacterial cell ranges between 70 and 85 %, and it decreases with increasing concentrations of reserve substances, such as lipids, polysaccharides, poly(β-hydroxybutyric acid), polyphosphates, and sulfur. The solids consist of protein (50 %), cell wall (10 – 20 %), RNA (10 – 20 %), DNA (3 –4 %) and lipids (10 %). The solid matter contains the percentages indicated of the following elements (among others): carbon (50), oxygen (20), nitrogen (14), hydrogen (8), phosphorus (3), sulfur (1), potassium (1), sodium (1), calcium (0.5), magnesium (0.5), chlorine (0.5), and iron (0.2) [15]. The density of bacteria is influenced greatly by the type and concentration of reserve substances. A high protein content results in a high density. The density may fall below 1 kg/L due to the deposition of lipids – to be expected in wastewater facilities subject to high loading.

Metabolism. Most bacteria utilize organic substrates as their sources of energy, hydrogen, and carbon; i.e., they are *chemoorganoheterotrophic*. These bacteria constitute the most important group of organisms useful for the degradation of organic substrates. Photosynthesizing cyanobacteria – formerly known as blue-green algae – absorb light as a way of meeting their primary energy requirement, utilize water or other (inorganic) compounds to meet their hydrogen requirement, and withdraw carbon dioxide from the environment to meet their carbon requirement. They are described as *photolithoautotrophic*. Many nitrifying bacteria trap inorganic sources of energy, hydrogen, and carbon, thereby classing among the *chemolithoautotrophic* organisms. Thiobacilli oxidize sulfides and other inorganic sulfur compounds as a way of obtaining energy and electrons. The obligatory chemolithoautotrophic thiobacilli utilize only carbon dioxide as a source of carbon, whereas the facultative autotrophic bacilli are also able to metabolize organic compounds [16], [21].

Ecology. Oxygen content is of tremendous importance in the activated-sludge stage, because oxygen is not only a substrate for respiration but also a source of toxic oxygen radicals. In addition, the carbon dioxide content also plays a role, especially because CO_2 lowers the pH. Most bacteria prefer pH values near the neutral point (pH 7). A few specialized bacteria tolerate extremes; e.g., sulfuric acid-forming thiobacilli tolerate a pH of 1 (acidophilicity). Most bacteria grow best at temperatures between 20 and 45°C, and are referred to as *mesophilic* organisms. Bacterial growth is retarded considerably in the cold, a factor that can interfere with the efficiency of wastewater treatment. Many bacteria are able to survive for years in the frozen state. Some extremely thermophilic archaeobacteria continue to grow at temperatures above 100°C, but die at low temperatures.

An optimal salt content for many freshwater bacteria appears to be ca. 3 %. Halobacteria thrive in salt concentrations >30 % [25].

Classification. In contrast to the natural or phylogenetic system, the common "artificial" system of bacterial classification presented in the

list below [29] is based not on degree of relationship but on morphological, physiological, biochemical, ecological, and other characteristics. These include shape, flagella, spore-forming ability, cell inclusions, pigmentation and capsule substances, staining properties, oxygen requirement, energy recovery, temperature and pH optima, applicable nutrients, reserve substances, cell-wall structure, sensitivity to antibiotics, pathogenicity and other relationships with respect to foreign organisms, and serological properties (for examples, see [30]). The nomenclature is binomial; i.e., each type is specified on the basis of a generic name followed by a specific name, the *epitheton* (e.g., *Escherichia coli*). The species are assembled in *genera*, the genera in *families* (with names ending in "-aceae"), and the families in *orders* ("-ales").

Group no.	Description
1	Spirochetes
2	Aerobic/microaerophilic, motile, helical, vibrioid gram-negative bacteria
3	Nonmotile (or rarely motile), Gram-negative, curved bacteria
4	Gram-negative aerobic rods and cocci
5	Facultatively anaerobic Gram-negative rods
6	Anaerobic gram-negative straight, curved, and helical rods
7	Dissimilatory sulfate- or sulfur-reducing bacteria
8	Anaerobic gram-negative cocci
9	Rickettsias and chlamydias
10	Mycoplasmas
11	Endosymbionts
12	Gram-positive cocci
13	Endospore-forming gram-positive rods and cocci
14	Regular, nonsporing gram-positive rods
15	Irregular, nonsporing gram-positive rods
16	Mycobacteria
17	Nocardioforms

Fungi. The terms *mycete* and *fungus* are derived from the respective Greek and Latin names for pileate fungi (mushrooms). These typical fruiting bodies are found on many treated clarification sludges, but not in the actual wastewater-treatment regimen.

Morphology [21], [25]. Fungi possess true cell nuclei, and like all the groups of organisms mentioned hereafter they are eukaryotes. Since fungi have cell walls and vacuoles, they are frequently classified as plants, even though they differ from plants with respect to a number of important characteristics. For example, fungi possess no photosynthetic apparatus, and they are always chemoorganoheterotrophic. Their poorly differentiated vegetative body (*thallus*) consists of branched threads (*hyphae*) ca. 5 µm in diameter. These in turn colonize the nutrient substrate and form the *mycelium*.

Reproduction. Fungal hyphae grow at their tips. Even small fragments of mycelium are capable of growing. Fungi multiply asexually by means of spores that are abstricted from the ends of the hyphae or formed in special receptacles. Yeasts multiply by budding. Almost all fungi also reproduce sexually. Higher fungi (see below), with a still unknown sexual form, are called "fungi imperfecti."

Classification. Distinctions are made between, among others, slime fungi (Myxomycota), Chytridiomycota, Oomycota, Zygomycota, and higher fungi (Eumycota), including ascomycetes, basidiomycetes, and imperfect fungi (deuteromycetes).

Ecology. Fungi colonize any space where other organisms exist or have left behind organic remains. As saprophytes they decompose the remains of plants and animals, spoil food, and infest wood, leather, paper, etc. As parasites they are dreaded pathogens, and their spores cause severe allergic reactions. In symbiotic relationship with algae or cyanobacteria they form lichen, which colonize cold environments. In symbiosis with trees (mycorrhiza) they act to improve the nutrient and water supply. In symbiosis with animals they metabolize otherwise indigestible foods. Their food is usually absorbed in dissolved form, and very seldom engulfed in particle form.

Only about 2 % of fungi live in water [21]. The Chytridiomycota are mainly aquatic fungi, and act as parasites of algae and water plants.

Among the aquatic Oomycota the genera *Saprolegnia* and *Leptomitus* form what is known as "water mold." Yeasts are ascomycetes, which among other things ferment nutrientrich liquids. Higher fungi play a role in the formation of the activated-sludge floc and the biological film, although excessive fungal growth leads to sludge bulking and clogging [25]. In the biological self-purification of surface waters, organic substances are degraded by such species as *Aspergillus niger, Fusarium aquaeductum, Leptomitus lactus*, and *Rhizopus nigricans* [26].

Plants. The term "plant" (Latin *planta*: seedling, shoot) refers not only to typical vascular plants (tracheophytes) such as club mosses, horsetails, ferns, and seed plants, but also to algae and mosses, which as prostrate plants (thallophytes and bryophytes) produce only a small number of differentiated tissue types.

Morphology. The plant cell is typically surrounded by a cell wall composed mainly of cellulose. Cell organelles that are especially conspicuous include the pigmented plastids (e.g., green chloroplasts for photosynthesis) and the vacuoles, which are the storage and waste compartments of the plant cell.

Metabolism. Algae absorb mineral nutrients and, to a small extent, organic substances across their entire surface [31]. Some flagellates engulf pieces of food. On the other hand, mosses and vascular plants take up water and salts by rhizoids or roots. As a result of their photosynthetic productivity, photolithoautotrophic plants constitute the basis of virtually all food chains. Roughly 60×10^9 t of carbon are channeled from the air and water into the biosphere by photosynthesis every year [32]. A few plants have lost their ability to perform photosynthesis, and now live as saprophytes or parasites. The flagellates are the closest organisms to the common ancestors of both animals and plants. Animal zooflagellates often differ from plant phytoflagellates only by the absence of chloroplasts.

Ecology. Most algae live in water, and mosses are usually limited to moist environments. Although horsetails, ferns, and especially seed plants have increasingly colonized drier locations, this category also includes various water plants (hydrophytes), marsh plants (helophytes), and plants that thrive in moist places (hygrophytes) [15].

Especially the algae are important with respect to water-pollution control. Typical algae populations grow in surface waters as a function of the pH, rate of flow, temperature, nutrient supply, lighting conditions, salt content, competitors, phytophagic species, and many other factors. A massive development of single-cell algae (e.g., *Ceratium fusus, Ceratium fruca, Chrysochromulina polylepis, Noctiluca miliaris, Phaeocystis pouchetii*) or cyanobacteria is referred to as "algal bloom" or, if red in color, red tide. They are responsible for the death of fish as a consequence of toxins they generate, oxygen deficiencies caused by respiration or their own biological degradation, poisonous mussels, and excessive foam formation. Algal bloom is sometimes associated with the eutrophication of a body of water (corresponding to an oversupply of fertilizer), but a regular succession of algal blooms in the North Sea [15] and other bodies of water has been found to be independent of the anthropogenic nutrient supply.

Euglenophyta are common in heavily polluted waters, oxidation ponds, and other nutrient-rich sites. They are tolerant of both large fluctuations in pH and anaerobic conditions, and are regarded as marker organisms for contaminated waters. The golden algae (Chrysophyta) include the genus *Synura*, which colonizes trickling filters and wastewater ponds. Many green algae of the order Volvocales live in eutrophic waters, including the family Chlamydomonadaceae, and they may even colonize specific types of wastewater (e.g., *Pandorina* and *Spondylomorum*, which colonize the wastewater from paper mills). Only a few types of green algae grow in the well-mixed, turbid activated-sludge stages of wastewater-treatment plants due to the lack of light. They are sometimes found inhabiting the inner walls near the water level. Upper layers of trickling filters that are exposed to light may be colonized by green algae of the genera *Chlorella, Chlorococcum, Stigeoclonium*, and *Ulothrix* [25].

In the presence of light, algae slightly improve the oxygen supply of the biological film. Oxygen produced by algae also substantially reduces the required residence time for wastewater in an oxidation pond. Small, spherical, green algae of the genus *Chlorella* are found in such ponds at all times of the year [25].

Mosses are typical inhabitants of environments that are poor in nutrients. Only in exceptional cases are they found at receiving streams contaminated with wastewater (*Marchantia* of the stone liverwort family), on slimy banks of ponds and rivers, and on trickling filters (*Leptodictyum* of the class Musci).

Higher plants do not normally grow in activated-sludge stages. Various rushes, bulrushes, grasses, and herbage thrive in polishing ponds, plant-wastewater treatment facilities or other wastewater ponds [14], [33], [34]. In particular, the sedges (Cyperaceae), with aerating tissue in their stems, are able to supply nutrient-rich sediments with atmospheric oxygen. In addition, bactericidal emissions from the roots have been reported. The unobtrusive sedge *Schoenoplectus lacustris* is already being introduced into numerous wastewater ponds, less frequently the reed *Phragmites australis*, one of the sweet grasses. Reeds are also used for the dewatering of clarification sludge because of their potential for oxygen transfer via the roots [35].

Animals. As a rule, animals are more complex organisms than plants, although they lack a cell wall, photosynthetic apparatus, and vacuoles [36]. Most animals are mobile, having become sessile only in water and as parasites. Various groups of small animals are of great importance in wastewater biology since they consume and metabolize bacteria, fungi, algae, and other types of biomass. The most important are as follows [21], [25], [36]:

1) Subkingdom Protozoa
   1. Flagellata
      - Protomonadina (often sessile)
      - Rhizomonadina (cilia as sensory organs, sessile)
   2. Rhizopoda
      - Amoebina (flowing-creeping, naked amoeba)
      - Testacea (shelled amoeba)
      - Heliozoa (skeletons with radiating axial rods)
   5. Ciliata
      - Holotricha (largely covered by cilia)
      - Spirotricha (cilia especially in the mouth region)
      - Peritricha (bearing a distinctive wreath of cilia)
      - Suctoria (tentacles)
2) Subkingdom Metazoa
   14. Nemathelminthes (round worms)
      - Rotifera (see text)
      - Nematoda (see text)
   20. Annelida (segmented worms)
   25. Arthropoda (segmented, joint-footed animals)
      - Crustacea (including crayfish, lobsters, crabs)
      - Insecta

Protozoa. Morphology [24], [25], [28], [36], [37]: Unicellular protozoans include flagellates, which are closely related to algae; rhizopodes (Sarcodina) which are distinguished by slimy projections (pseudopodia); and ciliates with two types of nuclei, which move and acquire food by means of cilia.

Ecology: Virtually all protozoans are capable of ingesting particulate food, especially bacteria, with the aid of specialized cell regions. Among the ciliates, for example, the slipper animalcule (*Paramecium*) whirls food into its mouth opening, Didinium numbs its prey with toxins from transformed cilia (trichocysts), and suctorians capture their prey with tentacles. Flagellates and ciliates are responsible above all for ingesting individual suspended bacteria and small particles that would otherwise enter into the effluent from a wastewater-treatment plant. Amoebas consume bacteria in activated-sludge floc and retard sludge formation.

Metazoa. The multicellular metazoans exhibit sensory organs as well as nervous, circulatory, digestive, and excretory systems, which frequently appear in reduced form in small organisms or highly specialized parasites [36].

Rotifera. Morphology [24], [25], [37]: The wheel animalcules (rotifers) are seldom larger than 0.5 mm, and their number of cells is fixed at a level usually attained after a few hours of growth. This is followed by an approximately one-day period of maturity. Rotifers acquired this name as a consequence of a corona of cilia surrounding the mouth area, which gives the impression of a rotating wheel. Within the group, the wheel organ (corona) can be transformed or simplified in diverse ways. The trunk is often sack-shaped, armored, and prickly. The head with its wheel organ and a telescope-shaped foot with adhesive glands can be withdrawn into the

trunk. Many species have a conspicuous masticatory (chewing) apparatus in the gizzard that operates constantly and is readily discernible.

Ecology: Many rotifers acquire nutrients by swirling; some also feed on activated-sludge floc, thus stimulating floc renewal. Rotifers frequently colonize small freshwater habitats that exist only for a short time. They are seldom found in the sea. When the water is drained off they survive by drying out and assuming a state of dry torpor. Free-swimming, fluke-like creeping, and sessile species are all known. In such wastewater-treatment facilities as aeration tanks, trickling filters, and oxidation ponds, the two orders Bdelloidea and Monogononta are particularly common.

Nematoda. Morphology: The free-living threadworms (nematodes) are spindle shaped, and only rarely longer than 3 mm [33], [37]. They are surrounded by a coarse shell (*cuticula*), which serves as an antagonist for the longitudinally oriented muscles. No transverse muscles are required. Nematodes wriggle in a strange manner; this mixes their body fluids, rendering a blood circulatory system unnecessary. A nematode can be identified above all by its mouth, mouthparts, and foregut.

Ecology: Nematodes live as parasites or saprophytes in substrates rich in nutrients and poor in oxygen, such as host tissue, fungi, sediments, or feces. They are poorly adapted to life in aqueous medium on activated-sludge floc. They reside in aerobic layers in the sediments of wastewater ponds or in the biofilms of trickling filters, supporting aeration and regeneration by their feeding activity [25].

Annelida. The segmented worms (annelids) are common in trickling filters. The earthworm is the best known representative of this class. Important species include *Enchytraeus coronatus* and *Lumbricillus lineatus*, which loosen the biological film and can even protect it from becoming clogged with sludge. The population density of annelids often depends on the population of trickling-filter flies (*Psychodae*). The fly larvae eat the worms and their eggs.

By contrast, the worm species *Tubifex* is encountered only rarely in trickling filters. It is regarded primarily as an indicator of the quality of surface waters [25].

Crustacea. Various small crustaceans are found in grade II and III surface waters, in the outflow from slightly loaded trickling filters, and in wastewater ponds. These creatures live as plankton and feed on detritus, algae, or other animals. They indicate water of relatively high quality [25].

Insecta. Two orders of insects are commonly found in trickling filters: springtails (Collembola) and flies (Diptera). The Collembola are omnivorous and colonize the biological film. The adult trickling-filter fly *Psychoda* is poorly equipped for flying, and actually belongs to the family of moth gnats, known for their fluttering flight. *Psychoda* larvae bore into the biological film and counteract clogging [33]. The mass reproduction of trickling filter flies is a nuisance, and can be controlled by a day-long flooding of the trickling filter [25].

High population densities of chironomids can also become problematic. The eggs, larvae, and pupae swim in jelly-like clumps on the surface of the water, interfering with the efficiency of the activated-sludge tanks [25].

2.1.1.2. Biocenosis

Not only free-swimming individual organisms, but also aggregates of organisms are found in wastewater and in treatment plants. To some extent these aggregates constitute highly organized communities (biocenoses), that are responsible for much of the biological degradation efficiency of a wastewater-treatment plant. All the various organisms, abiotic particles, and other suspended wastewater components in the thickened wastewater constitute the *activated sludge*, which typically contains about 1 % dry matter. The most important process-engineering parameter with respect to activated sludge is the sludge age, obtained by dividing the total mass of sludge dry matter by the amount discharged daily [33].

Activated sludge always contains bacteria. In industrial wastewater-treatment plants, for example, the following genera have been identified: *Acinetobacter, Aeromonas, Agrobacterium, Alcaligenes, Azotobacter, Bacillus, Brevibacillus, Chromobacterium, Enterobacter, Escherichia, Flavobacterium, Microbacterium, Micrococcus, Moraxella, Mycobacterium, Nocardia, Pseudomonas*, and *Zoogloea* [30]. Depending on the age of the sludge and its

load, populations of protozoans and metazoans may be established. In older sludge, the slow-growing nitrifying bacteria increase in importance (Fig. 6).

Some organisms swim freely in the wastewater, and others form typical aggregates that function as biocenotic teams. Depending upon appearance, a distinction is made between suspended activated-sludge floc, fixed biofilm, and (as undesirable forms) floating bulking sludge and fast-peeling biofilm.

Activated-Sludge Floc. Activated-sludge floc represents the smallest unit of biocenosis with a high potential for biodegradation of organic substances. The activated floc consists of bacteria, fungi, protozoans, and metazoans. The organic composition varies depending on the relevant ecofactors,such as operating conditions,wastewater composition, climate, season, etc. [24]. The diameter of the irregularly formed, spongy activated-sludge floc is typically 50 – 200 µm [39]. The floc is normally gray to brown in color. Floc is produced by bacteria that form slime shells or capsules, as well as by fungi. Especially valuable in this respect are, for example, *Bacterium aerogenes, Bacterium cercus, Bacterium proteus, Enterobacter aerogenes, Nocardia actinomorpha*, and *Zoogloea ramigera* [25]. Parts of the floc constantly become lost due to both turbulence and feeding. Flocs are regenerated by regrowth from fragments, and they are colonized by free-swimming organisms. Increasing floc size leads to a decrease in the oxygen and nutrient supply for organisms in the interior of the floc, causing their growth to stagnate. Ciliates are indicators of healthy flocs [39]. These can be determined on the basis of microscopic and physiological characteristics [24], [40]. Indicator organisms for monitoring floc status are identified in Figure 7 [25]. For municipal wastewater-treatment plants, a rule of thumb states that organisms associated with water-quality classes II and III are found in healthy activated-sludge flocs, and these for water classes III and IV are present in poorly functioning activated-sludge flocs. Organisms of the latter type include amoebas, flagellates, spirilla, rod-shaped bacteria, and slipper animalcules [25].

Bulking sludge is activated sludge in which the extent of activated-sludge floc is diminished relative to filament-like organisms [41]. Although the purification power of bulking sludge is good, its presence is undesirable in wastewatertreatment plants because of its poor separability [25], [33]. A rich food supply is available in a heavily loaded treatment plant. In the event that the carbon/nitrogen ratio is high [15], filament-forming microorganisms grow especially rapidly, storing large quantities of lipids, polysaccharides, and poly(β-hydroxybutyric acid). Moreover, the branched bacterial filaments and fungal hyphae readily retain gas bubbles. Malodorous gases are formed in the anaerobic zones associated with wastewater activation. The term "bulking sludge" refers to floating sludge that rises with visible gas bubbles, and is often related to odor production. Filament-forming bacteria, especially those belonging to the group actinomycetes, as well as fungi are responsible for the unwanted appearance of a viscous top scum [42]. Apart from *Spaerotilus natans, Microthrix parvicella,* representatives of the genus *Nocardia*, and other bacteria [43], fungi of the genera *Leptomitus* and *Geotrichum* have been identified [25]. Upon exhaustion of other nutrients, actinomycetes generate poly(β-hydroxybutyric acid) from excess carbon compounds that are present. Appearance of this phenomenon may also indicate the presence of high levels of sulfides [44], hydrocarbons, surfactants, organic acids, or alcohols in the wastewater, or perhaps the absence of adequate aeration. Filaments exhibit a relatively large surface area relative to flocs, so organisms living in the filaments are able to absorb dissolved substances more easily then those living in flocs. On the other hand, this hypothesis suggests that flocs have the advantage of more effective particle absorption, so an equilibrium should be established between flocs and filaments, the position of which would be a function of the state of the nutrient supply [25]. Sludge bulking is promoted by high temperatures and finely dispersed aeration [45].

Biofilm. A microbial coating forms on all solid surfaces that are in permanent contact with wastewater. This coating is called *biofilm* as a result of its manner of formation, or *microbial lawn* on the basis of its appearance. Biofilm has

Figure 6. Simplified schematic representation of the qualitative compositions of microbial biocenoses as a function of sludge age [38]

Figure 7. Indicator organisms present in activated-sludge floc [25]

a slimy feel. It is a gel consisting of extracellular organic polymers that enclose various microorganisms and other particles.

The formation of a biofilm, its strength, and its structure are determined by the medium (wastewater composition, temperature, pH), hydrodynamic conditions (shear forces, pressure), substrate (chemical composition, solubility, roughness, porosity, surface charge, hydrophobicity), and nature of the microorganisms present [44]. The only surfaces that remain largely uncolonized are those exposed to a very strong flow, surfaces that are extremely smooth, and surfaces from which biocides constantly diffuse into the water.

The symbiosis within a biofilm consists of bacteria, fungi, protozoans, and in most cases also metazoans and algae. Metazoans such as rotifers, threadworms, segmented worms, springtails, and fly larvae develop especially in lightly loaded treatment plants. Some metazoans are able to filter particles out of the wastewater, thereby improving the effluent quality. In particular, metazoans graze on the biofilm, thereby improving its aeration, sometimes increasing its biological efficiency, and reducing sludge formation. However, excessive amounts of metazoans cause the biofilm to become detached. Algae develop on exposure to light, and under favorable conditions they form distinguishable layers, similar to the colorful striped muds found,

for example, along the North Sea [46], which are formed and stained as a function of the supply of light, oxygen, and nutrients. Algae are also transported passively into the unlighted areas of trickling filters where some of them survive heterotrophically (e.g., the silica algae *Navicula cryptocephala*) [25].

In trickling filters, intermittently submerged reactors, oxidation ditches, wastewater ponds, or even natural waters, biofilms degrade a large share of the organic compounds present, and contribute significantly to self-purification. Consistent with the cleaning effect of trickling filters or intermittently submerged reactors, indicator organisms found on the influent side are characteristic of higher loads than those on the effluent side [25]. The biofilm itself is also not homogeneous. The concentrations of oxygen, nutrients, nitrate, and sulfate decrease from the surface to the base. The aerobic surface layer, with a thickness ≤ 3 mm, consumes the largest share of the nutrients and oxygen [33]. Below this layer is an oxygen-free (anoxic) layer containing nitrate, in which denitrification occurs. A sulfate-reduction layer may exist underneath this layer [14].

2.1.1.3. Metabolism

Metabolism (derived from the Greek word *metabole*: to turn about, change, convert [21]) encompasses the sum of all chemical conversions that occur within organisms, and even some reactions that occur outside the organisms as a consequence of excreted enzymes [47–49]. A distinction is made between *anabolism* (the synthesis of organic substance) and *catabolism* (degradative metabolism). *Primary* metabolism refers to metabolism directly required for life. *Secondary* metabolism refers to conversions that are not directly necessary for life, such as the synthesis of antibiotics. Metabolism in the context of ecochemistry is the degradation of substances that makes possible the growth of organisms, while *cometabolism* comprises degradation that occurs only in the presence of other easily usable substances [50].

The physical and chemical parameters in a wastewater-treatment plant must be adjusted in such a way as to permit a full spectrum of metabolic processes to occur. These biological conversions are by nature chemical reactions, and they are subject to the same natural laws as chemistry in the test tube. Conditions that must be maintained and the ways in which important metabolic processes proceed are described below.

Reactions and Catalysts. Almost all metabolic reactions are catalyzed by biogenic enzymes [48]. Enzymes, like industrial catalysts, only accelerate the establishment of equilibrium by reducing the corresponding activation energy; they do not change the position of equilibrium. Therefore, just as with industrial reactions, starting materials are always "left over" in metabolic reactions as residual materials. According to the law of mass action, there is never a complete conversion of material. As in industrial systems, however, the amount of residual starting material can become very small if the products are constantly removed or in some way utilized. Entire reaction sequences proceed according to this principle, with the result that only small concentrations of the many intermediates appear, even though the starting materials or end products may be present in large amounts. This is referred to as a dynamic equilibrium process. For example, every day a human being uses up about his or her own weight of adenosine triphosphate, a chemical equivalent of energy. However, at any given time the body contains only tiny amounts of this compound, which is continually regenerated [15]. This principle has significant advantages. Enzymes and cofactors required for the various conversions are used much more frequently, and are thus present in smaller amounts. Metabolism itself can be closely regulated via enzyme activity, appropriate coupled reactions, the introduction of intermediates (anaplerotic reactions), and regeneration of the cofactors.

Most enzymes (*holoenzymes*) consist of a protein component (*apoenzyme*) together with a permanently bound prosthetic group, or else they are reversibly bound to typical cosubstrates (*coenzymes*). Coenzymes serve as reaction partners for the substrate, and contain electrons or chemical groups present in an easily convertible form. Thus, instead of utilizing free hydrogen in reductions, enzymes take advantage, for example, of hydrogen available in the coenzyme nicotinamide adenine dinucleotide (NAD) in its

reduced form. Enzyme structures undergo reversible changes during the course of a reaction [48], [51]. The part of the enzyme that binds the substrate and catalyzes the reaction itself is called the *active site*.

The most important parameters influencing the activity of enzymes and organisms in wastewater-treatment plants are pH, temperature, and oxygen content.

pH. The ability of an active site to bind substrate and coenzyme depends on the states of charge or protonation of both the enzyme and its reaction partners. In addition, pH determines the water solubility of important gases, such as carbon dioxide, hydrogen sulfide, and ammonia. The pH also affects the bioavailability of heavy-metal ions and other materials. Extreme pH values can lead to the denaturation of proteins.

Temperature. Reaction partners reach the active site by diffusion, which increases with temperature. According to the Arrhenius equation, it is possible in the case of typical biochemical reactions to conclude that the fraction of the reacting components with energy equal to or greater than the activation energy roughly doubles with a 10 K increase in temperature. This is the case, for example, with many fermentations and reactions controlling bacterial growth.

Figure 8. Relationship between conversion rate and substrate concentration [48]

Oxygen. Oxygen is the most important electron acceptor for most organisms, and it is the medium that makes respiration possible in what is known as the *aerobic* or *oxic* state. If oxygen is lacking, the state is called *anoxic*. In the anoxic state, many microorganisms are able to utilize substances such as nitrate rather than oxygen (see Denitrification p 21). If nitrate too is lacking, the medium is described as *anaerobic*, and sulfate, carbon dioxide, or protons become subject to reduction, or organic substrates are fermented [52]. A table characterizing the metabolic activities of activated sludge as a function of the available electron acceptor is presented in Section 2.1.2 (Table 4).

Regulation and Adaptation. The degradation efficiency of a wastewater-treatment plant may continue to increase even after years of operation. The reasons for increasing adaptation of the microorganisms to their substrates and environmental conditions include:

1) Regulation or activation of the enzymes present; enzyme activities are subject to regulation within seconds or minutes.
2) Induction or the new formation of enzymes, with the time required being on the order of hours.
3) Appearance of new bacteria by mutation and/or plasmid transfer; the individual processes require seconds to hours, although effects are first discernible much later.
4) Selection and growth of adapted microorganisms, which occurs in the course of days to years.

Enzyme Regulation. The conversion rates of materials can be controlled via the catalytic activity of enzymes. In this context it is appropriate to take note of a few kinetic terms:

The *maximum rate* $V_{\max}$ of an enzyme-catalyzed reaction for the conversion of a substrate A to the product B ($A \rightarrow B$) is obtained with an unlimited excess of substrate (Fig. 8).

The substrate concentration that corresponds to one-half the maximum reaction rate $V_{\max}$ is equivalent to the *Michaelis constant*, K_{m}. The lower the value of K_{m}, the better the conversion at low substrate concentrations.

The *turnover number* or *molecular activity* indicates how many molecules of substrate are converted per molecule of enzyme per second.

A great excess of substrate does not lead to a correspondingly high level of material conversion. In a living organism, conversion rates depend rather on the enzyme characteristics K_{m} and activity. For this reason, regulation of many metabolic pathways starts with the enzymes:

In the case of *competitive* inhibition, a molecule similar to the substrate competes for the active center. The resulting inhibitory effect can be overcome by an excess of substrate.

Competitive inhibition increases the magnitude of K_m.

In *noncompetitive* inhibition the active center becomes damaged, and an excess of substrate is incapable of overcoming the observed inhibition. The value of V_{max} decreases in proportion to the fraction of damaged enzyme molecules.

Allosteric inhibition or activation is based on changes in the structure of the enzyme, whereby *effectors* (i.e., regulatory or inhibitory substances) bind outside the active site at what are known as allosteric sites.

Cooperativity is observed with enzymes that consist of several identical subunits. Cooperativity means that the subunits are turned on and off simultaneously whenever a single subunit is affected.

Enzyme Induction. Moving beyond the control of enzymic activity, entire metabolic pathways in organisms can be regulated by adapting the amount of available enzyme to the demands of the cell. Some level of enzymes is always present in the cell, catalyzing maintenance metabolism among other reactions. However, many enzymes are actually formed only in response to some chemical or physical signal. This process is called *induction*. For instance, bacterial enzymes that digest various sugars are inducible, as are heat-shock proteins. The advantage of induction is that it economizes on building blocks, but there is the disadvantage that it takes a relatively long time before newly formed enzymes become available. New formation can proceed only if an efficient primary metabolism is established, along with sufficient nutrient and reserve substances. Thus, in the case of the batchwise accumulation of wastewater components in a wastewater-treatment plant, an induction adaptation time of as much as several days should be anticipated.

Formation of Adapted Microorganisms. Bacteria are able to transfer DNA from one cell to another, thereby conferring certain characteristics such as degradation potentials.

In *conjugation*, a plasmid and sometimes also chromosomal DNA is transferred from a donor cell to a recipient cell. Conjugation is dependent upon "fertility" genes.

In *transformation*, a "competent" recipient cell accepts a DNA fragment from the medium and incorporates it into its own genome. Transformation is especially common in rapidly growing bacterial populations.

In *transduction*, a bacterial DNA fragment is transferred by means of bacteriophages [23].

DNA transfer has been observed not only between bacteria of the same species, but also between different species [53]. Bacteria from a receiving stream close to the discharge point display more resistance characteristics than bacteria from a load-free receiving stream [27].

Mutations may change genes in such a way as to generate improved enzymes. For example, as a result of mutation a *Pseudomonas* strain was better able to degrade polychlorinated biphenyls than the original (wild) type [54].

Selection. Growth and DNA transfer form the basis for the bacterial utilization of wastewater components and the degradation of this material in a biological wastewater-treatment facility. Given optimum living conditions, bacteria that contain plasmids grow more slowly than bacteria that do not. Consequently, wastewater components metabolized via a plasmid-coded degradation pathway must always remain in the biological stage of a treatment plant for longer periods of time in order to permit the build-up of plasmid-carrying bacterial populations. This process corresponds to natural selection. If the selected wastewater components subsequently disappear (e.g., because production is interrupted), the plasmid-free bacteria outgrow the plasmid carriers. Plasmids can also be eliminated "spontaneously," or become lost during fission [23], [28], [53], [55].

Carbon Oxidation. In the aerobic degradation of such organic substrates as fats (lipids), carbohydrates (polysaccharides), and proteins, the materials are converted with consumption of oxygen either to other organic substances (*biotransformation*) or to inorganic substances such as water, carbon dioxide, and ammonia (*mineralization*).

The degradation of organic compounds is linked through intermediary metabolism to the synthesis of cellular building blocks (Fig. 9). The degradation and synthesis of even complicated substances proceeds via a series of common C_4, C_3, C_2, and C_1 compounds. Two of the most important intermediates are shown in Figure 9: pyruvate, the salt of pyruvic acid, and acetyl CoA, an acetic acid residue bound to

coenzyme A [33], [48]. Carbon entering into metabolism in the form of usable organic compounds is not entirely discharged through respiration; at least a portion of it is incorporated into cellular substance [49].

Added carbon is converted almost completely to carbon dioxide only when the organisms in question have largely exhausted their own internal reserves. In a normally loaded activated-sludge stage, far more than one-third of the usable organic carbon is retained in the sludge, about the same amount is released through respiration, and a small part remains in the treated wastewater in the form of nonseparable organic substance. The latter comprises unconverted starting materials, free-swimming organisms, and degradation products of substrates and organisms (e.g., soluble or suspended humic matter).

Ammonification. Ammonification is a mineralization process that leads to the release of ammonia or ammonium ions from organic nitrogen compounds. In particular, bacteria and fungi liberate ammonia in the presence of a rich supply of organic nitrogen. This can be suppressed by the feeding of readily assimilable carbon compounds (see also Nutrientspage 25 and [38]). Plants lose ammonia in photosynthesis via small ventilation openings, the *stomata* [56]. Ammonotelic animals such as fish and amphibians also excrete ammonia into the environment [36].

Domestic sewage contains nitrogen largely in the form of urea, this being the anthropogenic excretory product since humans are ureotelic [36]. Indeed, nitrogen compounds are metabolized and ammonia is formed even in the waste-discharge system itself [57]. An undesirable ammonification process is the conversion of nitrate to ammonia (see also Denitrification page 23 and [49]).

Nitrification. The biological oxidation of ammonia via nitrite to nitrate is called *nitrification*. The most familiar example is that of the chemolithoautotrophic nitrifying bacteria. These bacteria meet their energy requirements by oxidizing ammonia to nitrite or nitrite to nitrate. No known bacterium is capable of oxidizing ammonia chemolithotrophically directly to nitrate. Nitrite-forming bacteria such as *Nitrosomonas, Nitrosococcus, Nitrosospira, Nitrosolobus*, and *Nitrosovibrio* [38] are ammonia oxidizers that produce nitrous acid or nitrite:

$$2\,NH_3 + 3\,O_2 \rightarrow 2\,HNO_2 + 2\,H_2O + 636\,kJ$$

Nitrite-forming bacteria are always associated with nitrate-forming bacteria. These in turn oxidize the toxic nitrite to nitric acid or nitrate:

$$2\,HNO_2 + O_2 \rightarrow 2\,HNO_3 + 184\,kJ$$

Nitrate bacteria belong to the genera *Nitrobacter, Nitrococcus, Nitrospina*, and *Nitrospira* [38]. When *Nitrobacter* encounters an inadequate supply of oxygen during nitrification, nitrite is instead reduced, with the formation of nitrous oxide, N_2O [58], [59].

Nitrification results in the consumption of ca. 4.6 g of oxygen per gram of ammonia nitrogen, a small part of which is recovered in anabolic biosynthesis. Since the final product is a strong acid, nitrification is also linked to the acidification of an activated-sludge stage [57], [60].

Only a few lithoautotrophic nitrifying bacteria are also able to live heterotrophically. Nitrifying bacteria fix carbon dioxide via metabolic pathways like those found in green plants. Indeed, the low usable energy output associated with ammonia and nitrite oxidation necessitates metabolic pathways that are not very energyefficient, such as reverse electron transport. Thus, the growth of chemolithoautotrophic nitrifying bacteria is slow, and actively nitrifying bacteria can only be established in sludge that is highly aged. The operator of a wastewater-treatment plant is faced with another problem as well: nitrite oxidizers are more sensitive than ammonium oxidizers to many (toxic) substances and to any decrease in the oxygen content or pH. Unfavorable conditions lead to the accumulation of nitrite.

The heterotrophic nitrifying organisms include such bacterial species as *Pseudomonas, Streptomycetes*, and *Arthrobacter*, as well as fungi of the order Aspergillacea. In addition to ammonia and nitrite, these are also able to oxidize organic nitrogen compounds. However, heterotrophic nitrification appears to proceed only at a low rate in the form of a cooxidation involving other substrates, so it results in no appreciable contribution to energy metabolism [61].

Figure 9. Examples of pathways and linkages in carbon metabolism

Denitrification. Microorganisms can process nitrate via a number of metabolic pathways, thereby reducing it to ammonia, nitrous oxide, or molecular nitrogen (dinitrogen).

The uptake of nitrate is called *nitrate assimilation* when the reduction product ammonia flows into an anabolic pathway to be used, for example, in amino acid synthesis. Nitrate is assimilated by many aquatic bacteria, fungi, and plants. Closely related to nitrate assimilation is the *dissimilative reduction* of nitrate, also known as *nitrate ammonification*. Nitrate assimilation by *Escherichia coli* leds to the liberation of excess ammonia [62]. In strict anaerobic nitrate ammonification, nitrate functions as the terminal electron acceptor [21]. Nitrate ammonification is capable of replacing sulfate reduction in sulfate-reducing bacteria [63].

Denitrification actually refers to the reduction of nitrate to atmospheric nitrogen:

$$10\,[H] + 2\,HNO_3 \rightarrow N_2 + 6\,H_2O$$

The intermediates are nitrite, nitrogen monoxide, and dinitrogen monoxide. The enzymes involved are reductases with names derived from the corresponding starting substances or appropriate intermediates [64].

Nitrate serves in heterotrophic energy metabolism as the terminal electron acceptor in an anoxic respiratory chain. In contrast to the nitrate reductases in nitrate assimilation, most denitrification enzymes are sensitive to oxygen (for an exception see [65]). Consequently, wastewater denitrification is practical only in the anoxic state.

Many types of bacteria are capable of supporting heterotrophic denitrification, though not all of them have the full complement of necessary enzymes. In the absence of nitrate reductase only nitrite can be denitrified. If dinitrogen oxide reductase is absent, nitrous oxide accumulates [38], [58], [66]. The liberation of dinitrogen monoxide, which affects stratospheric ozone, is also to be anticipated when:

1) At very high nitrate concentration the dinitrogen oxide reductase activity is no longer sufficient to reduce in situ all the dinitrogen monoxide.
2) As a result of sequential or, in this case, late enzyme induction, the amount of dinitrogen oxide reductase available is not yet sufficient.
3) The biosynthesis of dinitrogen oxide reductase is inhibited, for example, by oxygen.

4) Dinitrogen oxide reductase activity is inhibited by the toxic effects of such species as hydrogen sulfide, acetylene, or oxygen, or because the pH is too low [58], [67].

Easily degradable carbon sources are required for heterotrophic denitrification [68]. Thus, in the case of glucose:

$$5\,C_6H_{12}O_6 + 24\,HNO_3 \rightarrow 12\,N_2 + 30\,CO_2 + 42\,H_2O$$

In practice, nitrified wastewater is either returned to the raw wastewater, or it is suplemented with a substrate like methanol. Since heterotrophic denitrification consumes acid, denitrifying wastewater can be used to accomplish the neutralization of acidic wastewater. It also reduces the energy expenditure required for oxygen transfer, and compensates for a part of the energy expenditure associated with nitrification.

Apart from heterotrophic denitrifying bacteria, there also exist autotrophic bacteria that accomplish denitrification with the aid of inorganic electron donors. These include *Thiobacillus denitrificans* and *Paracoccus denitrificans*, which utilize sulfide, thiosulfate, or hydrogen:

$$8\,NO_3^- + 5\,S^{2-} + 8\,H^+ \rightarrow 4\,N_2 + 5\,SO_4^{2-} + 4\,H_2O$$

$$8\,NO_3^- + 5\,S_2O_3^{2-} + H_2O \rightarrow 4\,N_2 + 10\,SO_4^{2-} + 2\,H^+$$

$$2\,NO_3^- + 5\,H_2 \rightarrow N_2 + 4\,H_2O + 2\,OH^-$$

One species of *Beggiatoa* can oxidize sulfide, and *Gallionella ferruginea* is able to oxidize iron(II) [49]. Autotrophic denitrifying bacteria are probably irrelevant in the context of wastewater treatment.

Biological Elimination of Phosphorus. Phosphorus in the form of phosphate is an essential nutrient for all organisms. Bacterial biomass contains 2 – 3 % phosphorus in the dry matter; fungi contain 0.4 – 4.5 % [69]. Consequently, some phosphorus is always eliminated from wastewater together with the excess sludge. However, conventionally operated municipal sewage-treatment plants remove only about one-fourth of the phosphorus present in wastewater.

In addition to normal phosphate uptake, which is a function of growth, microorganisms assimilate phosphate beyond their actual requirements. Phosphates are stored by bacteria, fungi, and algae [31] in the form of polyphosphate [57], and by plants also as *phytin*, a calcium – magnesium salt of inosite hexaphosphoric acid [70]. Polyphosphates are microscopically visible in bacteria as inclusion bodies, also known as *volutin* or *metachromatic granules*.

A distinction is made between two types of polyphosphate storage: "overplus accumulation" and "luxury uptake." In overplus accumulation, restoration of the phosphate supply after a period of phosphate deficiency causes the microorganisms to take up more phosphate than they immediately require, but the excess is soon reduced in the course of further growth. In luxury phosphate uptake, especially if growth is limited by a nitrogen or sulfur deficiency, cells take up more phosphate than is required for growth even without the need for a prior phosphate deficiency. The resulting polyphosphates function as a source of phosphate and, under anaerobic conditions, also of energy. During growth, polyphosphate reserves normally accumulate. Polyphosphate storage of this type is found with such facultative-anaerobic genera of bacteria as *Acinetobacter* and *Moraxella*.

To increase the stock of polyphosphate-storing bacteria in a wastewater-treatment plant the activated sludge is exposed alternately to anaerobic and aerobic conditions. Polyphosphate-storing bacteria cannot grow under anaerobic conditions, but they are able to take up organic acids or alcohols, which they can metabolize and store [e.g., as poly(β-hydroxybutyric acid)]. The source of energy in this case is polyphosphate, which undergoes hydrolysis [49]. Phosphate is not retained in the cell, but is released into the wastewater. This process is called *phosphate redissolution*. The level of redissolution depends largely on the extent to which reserve substances are formed in the anaerobic phase. The anaerobic phase normally lasts 1 – 3 h.

In a subsequent aerobic phase the bacteria form polyphosphate, thereby withdrawing phosphate from the wastewater. In this aerobic phase the reserves laid down anaerobically serve as a source of both energy and carbon for accomplishing phosphate uptake. Thus, bacteria of this type grow more rapidly than aerobic bacteria, which are dependent on an uptake of organic compounds in the aerobic phase. The

more anaerobic redissolution of phosphate, the greater is the aerobic uptake of phosphate. Aerobic phosphate uptake always exceeds anaerobic phosphate redissolution, which means that a net elimination of phosphate is achieved [71], [72].

Nutrients. Optimal degradation is achieved in the treatment of wastewater only if in addition to usable carbon compounds the other necessary nutrients are available as well. Domestic sewage normally contains a balanced supply of nutrients. Industrial wastewater is clarified only after compensation for deficient substances or – better still – the addition of nutrient-rich domestic wastewater. An attempt should be made to reach an optimal BOD_5: N: P ratio of 100: 5: 1, and a C: N: P ratio of 100: 12: 3. Summaries suggesting somewhat different numerical values are presented in [44], [69].

Nitrogen. Nitrate, nitrite, ammonium, amino acids, and other metabolites can be utilized by most types of bacteria, even though group-specific preferences do exist. Some industrial wastewater-treatment plants employ readily degradable nitro compounds, aniline, or organic ammonium derivatives as sources of nitrogen. Denitrifying bacteria are able to accept nitrous oxide. Some bacteria reduce atmospheric nitrogen to ammonia. As in the case of nitrate assimilation, nitrogen compounds are taken up and metabolized to ammonia, which is incorporated first into amino acids, and then into a broad spectrum of nitrogen-containing organic metabolic products. In addition to the assimilative uptake of nitrogen, the dissimilative pathway is also significant (see also Denitrification).

Phosphorus. Phosphate is an essential part of the anabolism and catabolism of all organisms. Chemical species that can serve as sources include phosphate, oligophosphates, and simple phosphoric acid esters subsequent to enzymatic hydrolysis. In wastewater-treatment plants containing adapted organisms a number of fairly stable phosphorus compounds can be used as well.

Sulfur. All organisms require sulfur-containing amino acids like methionine and cysteine for protein synthesis, together with other sulfur compounds in small amounts [47]. Many bacteria, fungi, and plants take up sulfur in the form of sulfate, less frequently as sulfide, and synthesize amino acids on their own. Numerous animals are dependent on food sources supplying both amino acids and sulfur-containing vitamins. Bacteria dissimilatively utilize sulfate as an electron acceptor primarily when dissolved oxygen and nitrate supplies in the vicinity have been exhausted. Conversely, purple sulfur bacteria (among others) employ molecular sulfur and sulfides as electron donors [23].

Other Macronutrients. Ions such as magnesium, potassium, and calcium stabilize the three-dimensional structures of proteins and play a role in the regulation of osmotic properties. Magnesium is the central atom of the chlorophyll molecule, an important component for photosynthesis. Iron and other metals are found in the cytochromes of the respiratory chain, and in the oxidases of various degradation pathways. Animals also require substantial amounts of sodium, chloride, and fluoride ions. All of these substances are usually available in a wastewater-treatment plant at adequate concentrations. Iron and aluminum salts are frequently added to wastewater to induce the chemical precipitation of phosphate.

Trace Elements. Small amounts of several other elements are required for a number of purposes and by several enzymes. Examples include: boron (complexation of polyhydroxy compounds?), vanadium (nitrogen fixation), manganese (photosystem II), cobalt (ribonucleotide reductase, nitrogen fixation), nickel (methyl coenzyme M reductase), copper (cytochrome oxidase, phenol oxidase), zinc (dehydrogenases), and molybdenum (xanthine oxidase, nitrate reductase, nitrogenase) [17], [48]. These elements are sometimes required only by a subset of the organisms (e.g., boron, vanadium, and nickel), or by certain species in a bound organic state in the form of a vitamin (e.g., cobalt). An insufficient supply of trace elements is less common in wastewater-treatment plant than levels exceeding the toxic limiting concentrations.

Toxicity. "Poisonous character" and toxicity refer in a general way to effects experienced by organisms in the presence of specific chemical substances. Various toxic materials can be present in wastewater [73], resulting in undesirable consequences with respect to wastewater treatment. These include:

1) Inhibition in terms of individual enzyme activities

2) Inhibition of specific metabolic pathways
3) Inhibition of growth (a *microbiostatic* effect) – of nitrifying bacteria, for example
4) Death of certain organisms (a *microbiocidal* effect)
5) Selective pressures favoring undesirable organisms as manifested in sludge bulking

Representative reported data with respect to threshold concentrations for detectable damage to activated sludge are as follows [44]:

Substance	Inhibiting concentration (mg/L)
Cadmium (Cd^{2+})	2 – 5
Chromium (CrO_4^{2-})	3 – 10
Copper (Cu^{2+})	1 – 5
Nickel (Ni^{2+})	2 – 10
Zinc (Zn^{2+})	5 – 20
Chlorine (Cl_2)	0.2 – 1
Cyanide (CN^-)	0.3 – 2
Mineral oils	>25
Phenols	200 – 1000
Hydrogen sulfide (HS^-)	5 – 30

The potential effect, and thus the toxicity, of a substance within a wastewater-treatment plant is not a predetermined constant, but is a function instead of the conditions of exposure and the organisms present (Table 2).

There is no such thing as toxicity per se. The term toxicity really refers to an interaction between some substance and a specific organism, which means it is subject to environmental influences. The substance itself merely represents the potential for a reaction.

The amount of a substance taken up by a particular organism is defined as the dose. Under stipulated exposure conditions it is sometimes more convenient to report a concentration in the case of gaseous or liquid media rather than a dose. Not the presence of a substance but the dose taken up of its biologically active form determines the effects. Many substances have never been shown to have any favorable effects whatsoever on organisms. However, in the case of heavy metals, several elements are now known to be essential at trace levels, despite the fact that they are toxic in high doses. The simultaneous action of several substances may lead to an alteration of effects (*coergism*), in which the resulting effect is either larger (*synergism*) or smaller (*antagonism*) than the sum of the expected effects of the individual compounds [15], [75], [76].

The physical distribution and chemical bonding state of a substance in the environment determines its rate of uptake and metabolism by an organism; this is known as its *bioavailability*. Poorly soluble (precipitation) products, substances adsorbed tightly on minerals, and other inert materials usually show no significant toxic effects.

The way in which a wastewater load is fed into the system is often decisive with respect to the behavior of a wastewater-treatment plant. A distinction can be made between two important feeding patterns [25]:

1) Irregular introduction of slugs of highly contaminated wastewater, usually a consequence of some disturbance of industrial batch production or, in an agricultural region, of seasonal production.
2) Continuous feeding of material residues in low concentrations, for example, following some form of wastewater pretreatment.

In the case of irregular feeding, even readily degradable, soluble organic compounds may be responsible for increased effluent values or sludge bulking. With continuous feeding of low concentrations of "toxics," the inhibitory effect soon diminishes due to adaptation, leading in fact to the growth of microorganisms displaying increased resistance and a higher degradation potential.

Degradation of Xenobiotics. The term xenobiotic is derived from the Greek words *xenos* (foreign) and *bios* (life), implying that xenobiotics are not formed biologically, but instead arise through industrial processes [14]. More and more metabolic pathways and organisms have been found to synthesize typical xenobiotics, especially organohalogen compounds [15], [77], [78]. Based on the assumption of an exclusively abiotic origin it is frequently deduced that xenobiotics cannot be biodegraded; nonetheless, the biodegradation of several such "xenobiotics" will be described below. Among all the substances still referred to as xenobiotic, the term as defined above probably applies only to a small subset of compounds. Used in this loose way it serves primarily as evidence of human ignorance. The term is employed in this contribution only to indicate that the substances

Table 2. Factors influencing effects of a substance (adapted from [74])

Substance	Environment	Organisms

[c] BOD/TOD, 10 – 25 %.
[d] BOD/TOD, <10 %.

in question are not derived from the same organisms that degrade them. In this sense, nutrients and vitamins are examples of xenobiotics for organisms that require them [15].

Like toxicity, biodegradability is also not a function exclusively of the substance itself, but is instead determined by a combination of organisms and abiotic environmental factors. In the presence of ordinary activated sludge, for instance, cellulose is not microbiologically degradable under normal conditions [33]. Some of the factors upon which degradation depends are:

1) The organisms, their arsenal of enzymes [79], and their adaptation potential [80].
2) The physiological state of the organisms and their supply of nutrients, trace elements, and vitamins.
3) The growth status of the organisms.

4) Environmental parameters such as pH, salt content, supply of electron acceptors, and temperature.
5) Substance concentration, since the rate of degradation exhibits an optimum value at a particular concentration of substrate; at very low concentration, for example, enzyme induction does not occur [81], whereas high concentrations result in toxicity [82].
6) The presence of other organic compounds.

If several substances are subject to degradation simultaneously, the observed degradation rates are usually not identical [33]. In fact, degradation of diverse but similar substrates seldom occurs simultaneously, but is most often successive [83] because of the ecological principle that energy and raw-material expenditure is minimized. This means that only one set of enzymes is synthesized rather than two. Consequently, processing of the more easily degradable substance initially inhibits the degradation of other substances (*diauxie*) [33]. On the other hand, in the case of cometabolism a poorly degradable material is degraded alongside a suitable, more easily degradable substance.

To determine a level of biodegradability, the substance to be examined (the test substance) is added to cultures of specific microorganisms, activated sludges, or other biocenotic systems. In a *direct* degradation test, disappearance of the test substance is measured after a period ranging from a few days to months. Tests of this type are also called "die-away tests." In *indirect* tests one measures the consumption of a substrate like oxygen, or the formation of some degradation product like carbon dioxide, hydrochloric acid, or ammonia rather than the test substance itself. The *biological oxygen demand* (BOD) is often determined as a wastewater quality criterion that is not substrate specific. The BOD is the mass of oxygen required for biological oxidation of the organic wastewater components that can be degraded by microorganisms in standardized wastewater [15], [84–87]. Indirect tests have the disadvantage that many substances are consumed also through anabolism in the course of forming endogenous substance, resulting in data reflecting an unrealistically low degree of degradation. If the test substance is the only usable carbon source present, its biodegradability can be established from the increase in the number of microorganisms. Biodegradability can also be predicted on the basis of structural characteristics and water solubility [88].

A few examples of substances degradable in wastewater-treatment plants are presented in Table 3 [49]; for further examples see [89], [90].

Enzymes that incorporate oxygen or hydroxyl groups into organic compounds play an important role in aerobic degradation. Depending upon the reactions catalyzed, the following distinction can be made [where X = xenobiotic, D = (other) hydrogen donor, A = (other) hydrogen acceptor] [15], [91–93]:

Oxygenases (dioxygenases)

$$X + DH_2 + O_2 \rightarrow X(OH)_2 + D$$

$$XH_2 + O_2 \rightarrow X(OH)_2$$

Monoxygenases (hydroxylases)

$$XH_2 + DH_2 + O_2 \rightarrow XHOH + D + H_2O$$

Dehydrogenases

$$XH_2 + A + H_2O \rightarrow XHOH + AH_2$$

Lyases

$$X + H_2O \rightarrow XHOH$$

Some xenobiotics can be channeled into primary metabolic pathways after a few preliminary reaction steps; for example, alkanes are first oxidized to alcohols and then processed further by β-oxidation (Fig. 9). Cleavage of appropriate substituents often permits carbon compounds bearing functional groups or substituents to be transformed into substances that can be dealt with by primary metabolism. For this reason, the discussion here will focus on the elimination of selected substituents rather than complete degradation pathways.

Aromatic Compounds. The key substance for the microbial degradation of aromatic compounds is catechol, which is in turn subject to catabolism and anabolism after an initial ring cleavage (Fig. 10). Several of the enzymes responsible for oxidizing aromatic compounds

show little specificity. These polyfunctional enzymes are able to convert various aromatics to catechol [94], its derivatives [95–97], or its precursors [98]. The enzyme-producing organism is thus able to metabolize a broad spectrum of aromatic compounds with little effort, which is significant, because aromatic compounds often occur in groups.

Figure 10. Microbial degradation of aromatic compounds [94]

Resonance, inductive effects, and steric effects all play a significant role in the degradation of aromatic compounds. The pH is important especially in the case of derivatives of aniline and benzoic acid. The rate of degradation of substituted aromatic compounds increases mostly in the presence of hydroxyl, carboxyl, carbonyl, and, often, alkyl substituents. It usually decreases in the presence of nitro, amino, chloro, and sulfonyl substituents. As far as disubstituted benzene derivatives are concerned, *para*- and *ortho*-substituted systems are usually degraded most readily.

Organic Halogen Compounds. Halogen removal (dehalogenation) is catalyzed by various enzymes, including oxygen-dependent dioxygenases and monoxygenases as well as oxygen-independent dehalogenases (reductases) and hydrolases [15], [55], [99]. Reductive dehalogenation, especially of the type occurring in anaerobic media, permits organohalogen compounds to replace oxygen as the electron acceptor. Various dioxygenases that degrade aromatic organohalides first attack the aromatic ring, usually at neighboring unsubstituted positions, which are then hydroxylated (Fig. 11) [99–101]. The biodegradation of polychlorinated dibenzo-*p*-dioxins and other organohalides can be catalyzed by lignin-degrading enzymes, where radicals formed from hydrogen peroxide serve as the oxidizing agent [102–104].

Nitro Compounds. Two degradation pathways are important here: reduction of the nitro group and direct cleavage of the C – N bond.

In the case of reduction, amino groups remain in the product, and their further degradation depends on the availability of hydrogen at the α-carbon. The presence of such hydrogen facilitates oxidative formation of an imino group, which is in turn hydrolyzed through the addition of water and elimination of ammonia. Reactions of this type also occur in amino acid metabolism. Many aromatic nitro compounds are reduced to aniline derivatives [105]. Figure 12 shows an example of the degradation of an aromatic nitro compound; the reduction of 4-nitrotoluene, which proceeds via nitroso and hydroxylamino intermediates [106].

Monoxygenases and dioxygenases catalyze direct removal of the nitro group in the form of nitrite [107–109]. Lignin-degrading enzyme systems similarly eliminate nitro groups as nitrite [110]. Examples of the degradation of industrially important nitroaromatic compounds are provided in [111].

Aromatic Sulfonic Acids. Dioxygenases cleave aromatic sulfonic acids to produce sulfite, simultaneously forming a catechol derivative (Fig. 13) [112–114]. Various bacteria and

green algae accept naphthalenesulfonic acids as sources of sulfur [107]. Toluenesulfonic acid is also degraded by aquatic plants [115].

Biological Elimination of Heavy Metals. Heavy metals may be present in wastewater in both the dissolved and undissolved state. In the dissolved state they form complexes with such species as water, carbonate, cyanide, and chloride, or with chelating agents like ethylenediamine-tetraacetic acid (EDTA), nitrilotriacetic acid (NTA), and citric acid. In undissolved form they are adsorbed onto particles, precipitated as salts, or included within other precipitation products. Suspended heavy metals are frequently bound to humic substances whose particle size and surface charge prevent their sedimentation. Several heavy metal complexes are always present simultaneously. These complexes are subject to interconversion, and are influenced by pH, temperature, redox potential, and the presence of other substances. In wastewater, precipitation, adsorption, and complex formation all occur in parallel with dissolution, desorption, and coordination change.

The biological elimination of heavy metals has been attributed to several different mechanisms [101]:

Sorption. Cell walls, slimes, and capsules associated with living organisms, together with their degradation products, macromolecules like proteins and polysaccharides, and humic substances all act as adsorbents, especially as a consequence of their polar groups. Carboxyl, sulfonic acid, amino, and phenolic groups act as ion exchangers that bind heavy-metal ions as a function of the pH and neutral salt concentrations, among other factors. Living cells adsorb various heavy metals and accumulate them. Large amounts of organic substances are bound to activated sludge by sorption [116–119].

Precipitation. Sulfide is formed in anaerobic zones of biofilms, leading to poorly soluble precipitates. Nevertheless, heavy metals are able to reach these sulfidic zones only slowly. More soluble precipitation products are formed in aerobic layers or activated sludges, but these precipitates are easily included in the growing biomass.

Complexation. Heavy metals existing as stable complexes are neither biologically available nor the cause of toxic reactions. Many microor-

ganisms, especially the heavy-metal-resistant organisms, synthesize and store complexing agents such as the iron-containing protein ferritin and the siderochromes (iron trihydroxamates) like ferrichrome [75], [120].

Figure 13. Degradation of 5-, 6-, 7-, or 8-substituted aminonaphthalene- or hydroxynaphthalenesulfonic acids by *Pseudomonas* sp. strain BN 6, and the assimilation of salicylates by other bacteria harboring complementary catabolic sequences [113]
X = $-NH_2$ or $-OH$

Methylation. Methylcorrinoid derivatives, better known as vitamin B_{12} derivatives, are capable of transferring methyl groups to such heavy-metal ions as mercury(II) [75]. These reactions would lead to the formation of toxic compounds in a wastewater-treatment plant, some of which would contaminate the off-gases. A number of reactions and metabolic pathways have been postulated for the biological methylation of heavy metals, but their relevance is still disputed [121].

Other Reactions. Microorganisms can metabolize and accumulate selenium in place of sulfur, arsenic in place of phosphorus [75], and cadmium in place of calcium. The reduction of vanadium, selenium, silver, and other heavy-metal ions is regarded as a mechanism by which these ions are eliminated from wastewater [122]. Microorganisms also take up heavy metals as trace elements necessary for life, incorporating them into coenzymes and other compounds [48].

The great importance of biological heavy-metal elimination is apparent from the brownish-black biofilms found in siderotrophic waters poor in nutrients, in iron drinking-water pipes, and in acidic wastewater from the mining industry. These films are due mainly to bacteria that oxidize iron(II) and, less frequently, manganese(II). Some "sham" iron bacteria have been found to live chemoorganotrophically, storing iron hydroxide in their capsules. True iron bacteria like *Thiobacillus ferrooxidans, Sulfolobus acidocaldarius,* and *Gallionella ferruginea* thrive chemolithotrophically [19], [123].

2.1.2. Basic Biotechnological Considerations

The early 1950s witnessed an economic upswing that led to increased production and the creation of more jobs, but on the other hand also resulted in increasing loads of industrial wastewater. Growing prosperity also meant greater public demand for hygiene. Sewage systems were expanded in many municipalities, but often without corresponding increases in wastewater-treatment capacity. All these factors resulted in more pollution of surface waters, and the resulting self-purification phenomena altered the natural oxygen balance. With the ensuing oxygen deficit came a deterioration in water quality, a decrease in the variety of aquatic organisms, and the death of many fish.

As a consequence, political pressure grew for the prevention of water pollution. Concerted efforts were initiated to somehow eliminate those biodegradable substances that led to a depletion of dissolved oxygen in surface waters.

Aerobic biological wastewater treatment is now the method of choice for elimination of these materials, whose levels are usually measured in terms of the biological oxygen demand (BOD) [87]. This is a long-established approach for the treatment of municipal sewage, but adaptation was required before it could be applied to industrial wastewater, especially wastewater from the chemical industry. This in turn dictated

that special demands be imposed regarding the wastewater itself.

Demands Applicable to Wastewater Quality. Intensive study of the problem revealed that a specific wastewater regime would be required from both the technical and ecological points of view. This led on one hand to separation of the wastewater into one waste stream requiring special treatment and another for which this was unnecessary, as well as separate transport systems. Qualitative considerations argued in favor of decentralized pretreatment based on physicochemical processes (discussed in detail below) as a way of eliminating those substances that disturb or inhibit biodegradation [7], [11], as well as centralized chemical and mechanical pretreatment within the wastewater-treatment plant in order to neutralize and eliminate undissolved substances.

Decentralized wastewater treatment facilitates the specific removal of substances that inhibit or disturb biodegradation based either on precipitation and subsequent separation or detoxification by oxidative treatment.

Over the course of time, increased knowledge has permitted requirements related to water-pollution control to become ever more strict. Oxygen balance is now not the only goal of water protection measures. Requirements have also become necessary to meet the demand for drinking water, mandating the virtual exclusion of organic substances – even substances subject to slow biodegradation. Consequently, the key parameter was no longer the BOD, but rather the chemical oxygen demand (COD) [124]. In addition, ecological concerns required the elimination of nitrogen and phosphorus compounds that tend to encourage eutrophication.

Thus, the overall demands currently imposed on wastewater quality are quite stringent. Substances that undergo slow biodegradation must now be removed in decentralized facilities engaging in specific pretreatment measures, or else converted into other, more readily biodegradable substances by means such as partial oxidation. Furthermore, it became necessary to introduce decentralized pretreatment processes directed toward the specific elimination of nitrogen and phosphorus, or else modify the biological wastewater-treatment stage in such a way as to ensure further removal of nitrogen (nitrification [125], denitrification [126]) and phosphorus (biological elimination [127] or simultaneous precipitation [52]), which entailed enormous developmental effort.

Demands Related to Microorganisms. The prerequisite for successful biological wastewater treatment is the presence of suitable microorganisms capable, perhaps after adaptation, of providing metabolic pathways for the degradation of various substances, and suitable for safe establishment at adequate levels in the biocenotic system of a biological wastewater-treatment plant (mixed sludge). Growth kinetics and mechanisms of flocculation and adsorption play a considerable role, and it is crucial that these organisms not be displaced by others in the necessarily nonsterile conditions characterizing a wastewater-treatment plant.

Hence, the biotechnological processes for aerobic wastewater treatment are based on the ability of bacteria on one hand to adapt to diverse wastewater components as their source of nutrients, but also to undergo aggregation (floc formation) in times of low nutrient supply [7].

Consider the way a biological system develops with time in the course of a batch experiment (discontinuous). In what is known as the "lag phase" the bacteria become accustomed to the nutrient substrate (*adaptation*). During a subsequent "log phase" the number of bacteria increases rapidly, and the nutrient substrate is quickly depleted. In this phase the bacteria are present as free-swimming entities, because there is still a sufficient amount of substrate available. Only when the substrate has largely been consumed will the bacteria tend to agglomerate.

Figure 14. Developmental patterns for the number of bacteria N and the substrate concentration S over the course of a batch (discontinuous) experiment

Biological wastewater-treatment plants are operated near the equilibrium-phase/death-phase boundary. This facilitates retention of the microorganisms while maintaining the lowest possible outlet concentration of the substrate, consistent with substrate degradation being the primary goal of wastewater treatment (Fig. 14).

Demands Made in Terms of Process Engineering. With respect to process engineering, three requirements must be met in taking advantage of the aerobic metabolism of microorganisms for biological wastewater treatment in such a way as to produce the highest possible space – time yield (i.e., treatment in the smallest possible volume over the shortest possible time):

1) The number of suitable bacteria must be as high as possible inside the available volume; i.e., the bacteria must be specifically retained by either internal or external means, depending on the process.
2) The bacteria must be provided with a sufficient supply of dissolved oxygen (i.e., there must be adequate aeration), where oxygen diffusion is enhanced by maximizing the extent of the gas – water interface.
3) The three reaction partners – bacteria, organic substrate, and dissolved oxygen – must be brought together, which requires carefully engineered turbulence.

These boundary conditions are not completely independent, and they have provided the impetus for various biotechnological approaches to the aerobic treatment of wastewater, including the trickling filter and the activated sludge-process.

Bacterial Retention. For economic reasons, efforts must be made to achieve the highest possible space – time yield in any industrial operation. Therefore, one of several process-engineering requirements associated with a biological wastewater-treatment plant is the presence of the highest possible number of active microorganisms within the reaction volume. Normally, bacterial growth in the course of the biological degradation of wastewater components is insufficient to guarantee a high concentration of bacteria in the bioreactor. Most biological wastewater-treatment plants are operated in a continuous mode, and thus constitute dynamic systems. Bacteria are constantly being discharged along with the purified effluent water. Bacterial growth within the reactor will compensate for loss of bacteria in the outflow only in the special case of a wastewater stream very heavily loaded with rapidly biodegradable substances. However, a system of this type would be in the log phase with respect to bacterial growth; i.e., the bacteria would be free-swimming and not separable, and degradation of the substrate would be incomplete. Such a fermenter can therefore be used only for biological pretreatment [128].

For this reason, all wastewater-treatment plants are instead operated with deliberate bacterial retention and bacterial separation. This is necessary as well for assessment of the effluent and efficiency of the plant from the standpoint of discharge licensing requirements. Bacteria in the effluent are monitored analytically in terms of substance removable by filtration, COD, and nitrogen and phosphorus content.

Bacterial retention and separation are both positively influenced by the growth and agglomerating power of the microorganisms in the equilibrium/death phase. Bacterial retention also results in the bacteria remaining in contact with the wastewater and its components over long periods of time, permitting the organisms to adapt accordingly.

Internal Bacterial Retention. If the bacteria are presented with the largest possible appropriate surfaces for growth within the bioreactor, then growth on these surfaces will in fact occur, leading to biofilms. These surfaces may be permanently installed as fixed or movable arrays, or they may consist of free-floating objects that are confined within the bioreactor in some convenient way. Processes based on this principle include the trickling filter, the intermittently submerged reactor, the biofilter, the loop reactor, and the Linpor device. Especially suitable growth surfaces are porous and rough, as for example lava slag, certain plastics (PVC, PU), sand, coke, and expanded clay [129]. Plant-based wastewater-treatment works [122], [130–132] also fall within this category, although they are applicable only for small amounts of wastewater. The biodegradation of organic substances is carried out in this case by microorganisms that colonize the surfaces of the plants.

Among the prerequisites for implementation of such biotechnological process are exclusion of solids from the inflow to the bioreactor, taking advantage, for example, of a prior mechanical purification step and targeted control of the hydraulic and waste loads as a way to prevent clogging due to bacterial growth.

Excess bacterial mass is detached from the growth surfaces by means of a hydraulic shock load, and then isolated from the effluent in the form of excess sludge, often by sedimentation, for further preparation in the sludge-treatment stage (see Fig. 29).

The *sequencing batch process* represents a special case of internal bacterial retention. This can be regarded as a transition process in the direction of external bacterial retention, because it also takes advantage of the floc-building capacity of microorganisms, which agglomerate into flocs in the equilibrium phase. The sequencing batch reactor (SBR) is operated discontinuously, as suggested by its name. Mechanically pretreated waste-water is introduced into a prepared bacterial suspension. After the completion of biological elimination processes all mixing is discontinued, providing the suspended flocculated bacterial mass with sufficient time to sediment. This is followed by phase separation within the reactor and subsequent withdrawal and redirection of the clear phase. Processing is resumed with renewed introduction of wastewater into the remaining bacterial suspension.

External Bacterial Retention. With an aerobic biological process in the absence of specific bacterial retention in the reactor, a continuously operated system soon becomes depleted of bacterial mass, because more bacteria are ordinarily discharged in the effluent than are formed through biological degradation. To prevent this negative effect, the process is divided into two steps. Biological degradation – the first process step – is followed by a second step: solid – liquid separation of the effluent on the basis of sedimentation, flotation, or filtration. This approach is feasible because the bioreactor operates in its equilibrium phase, so the bacteria aggregate into flocs. The externally retained bacterial mass is returned as required to the bioreactor in the form of recycled sludge (Q_{RS}). Excess bacterial mass is withdrawn as surplus sludge, which must then be appropriately prepared in the sludge-treatment stage (Fig. 15).

Figure 15. The activated-sludge process Q = wastewater; Q_{RS} = recycled sludge

Figure 16. Horizontal-flow post-clarification conducted in a rectangular basin

Figure 17. Vertical-flow post-clarification based on a Dortmund tank

Sedimentation. The sedimentation process takes advantage of a difference in density between the activated-sludge floc and purified wastewater (see also Section 5.2.2.1). The sedimentation rate is a function not only of difference in density, but also of the particle size and the viscosity of the wastewater (Stokes law).

Sedimentation may be allowed to proceed in flow aggregates arranged either horizontally (rectangular or circular sedimentation basins) or vertically (Dortmund tanks).

With a horizontal-flow clarifier the sedimented clarification sludge is compacted on the bottom by sludge collectors and either returned to the activation step or withdrawn as excess

sludge (Fig. 16). In a Dortmund tank, one example of a vertical-flow clarifying system, mechanical collection is unnecessary, because the geometric design of the cone (angle ca. 60°) permits the activated sludge suspension to flow by itself (Fig. 17).

The quality of the activated sludge is a decisive factor with respect to its possible concentration. This quality can be assessed on the basis of the *sludge volume index* (reported in cm^3/g after a settling period of 30 min) [133]. Flocculation and sedimentation characteristics can sometimes be improved by the addition of flocculation aids as necessary.

The potential bacterial concentration in an aeration tank is a function of the concentration process. If the activated sludge can be concentrated to a value of x (g/L), and the reflux ratio is 100 % [return flow (Q_{RS}) = inflow (Q)], an activated sludge concentration equal to $0.5\,x$ (g/L) plus the bacterial mass produced in the course of biological degradation is established in the bioreactor. Consequently, it is the sedimentation and concentration properties of the activated sludge that determine the space – time yield of the process. For this reason sedimentation is applicable only to activated sludges with low sludge-volume indices (~50 – 200 cm^3/g). With higher sludge indices (bulking sludge, threadlike growth [41], [42]) or to meet special requirements, flotation or filtration is used instead.

Flotation [134–136] (see also Sections 3.1 and 5.2.2.3) takes advantage of the tendency for substances suspended in water to adsorb gas bubbles at their surfaces. The suspended substances thereby become lighter than water, float, accumulate at the water surface, and can be skimmed off.

There are two prerequisites that must be met for successful flotation:

1) Adequate adhesion of gas bubbles to the surface of the suspended substances, encouraged as required by the addition of flotation aids.
2) Creation of the finest possible gas bubbles in the water by aeration flotation (Königsbacher [137]), dissolved-air flotation (Bitburger 2.134]), or pressurized dissolved-air flotation.

Advantages of activated-sludge separation by flotation relative to sedimentation are discussed in the literature, and include higher concentration of the activated sludge as well as reduced sludge residence time in the second process step, solid – liquid separation, which helps to prevent anoxic conditions.

Filtration. Ultrafiltration represents a special case of sludge retention downstream from a bioreactor [139]. Especially high concentrations of activated sludge can be achieved with this approach. When combined with a closed biological system this method is also applicable to the degradation of volatile materials (e.g., chlorinated substances). However, the effective range of application of biology coupled with ultrafiltration so far limits the approach to relatively small wastewater streams.

Provision of Oxygen. In order for aerobic biological degradation to be successful the bacteria in the bioreactor must have access to an adequate supply of oxygen. This normally entails oxygen dissolved in the water (DO), but in special cases, oxygen-containing materials such as nitrate (denitrification) or hydrogen peroxide may serve the same purpose [140].

Effective mass transport through the interfaces gas – water and water – bacterium is crucial for supplying the microorganisms with dissolved oxygen. Oxygen for conversion by bacterial metabolism must first be transported through the gas – water interface and dissolved in the water before it becomes available to the bacteria. This mass transport is in turn a diffusion-controlled process (Fig. 18).

Figure 18. Material interchange at the gas – water and water – bacteria interfaces
DO = dissolved oxygen; DCO_2 = dissolved carbon dioxide

The solubility of oxygen in water depends on both the temperature and the oxygen partial pressure of the gas. According to Henry's law:

$$p = K\,c$$

where p = partial pressure, K = a temperature-dependent constant, and c = concentration in the liquid.

Dissolved-oxygen values for air (O_2 = 20.8 vol %) at 1 bar in salt-free water are as follows [141]:

°C	Dissolved oxygen (mg/L)
5	12.37
10	10.92
15	9.76
20	8.84
25	8.11
30	7.53

Oxygen transport through the gas – water interface depends on the extent of the available interface and on the concentration gradient required for diffusion. It is described by the expression [136]:

$$G = k_L A \Delta c$$

where G = mass flow through the phase boundary (e.g., kg of O_2/h), k_L = oxygen transfer coefficient on the liquid side (e.g., m/h), A = area of the phase interface (e.g., m^2), Δc = concentration gradient (e.g., g of O_2/m^3) = $C_S - C_O$ (in the simplest case), with C_S = saturation concentration and C_O = current system concentration.

Figure 19. The trickling-filter process
Q = wastewater; Q_R = recycle water

Oxygen input normally occurs directly within the bioreactor. The requisite exchange surface between the gas – usually air; in exceptional cases technical-grade oxygen – and the wastewater is produced deliberately in the presence of the microorganisms. With a trickling filter (a type of packed column), wastewater is sprayed in from the top onto a set of internal fittings (growth surfaces). It then flows downward in a thin layer over the previously developed biofilm, permitting oxygen exchange with gas that is flowing countercurrently (Fig. 19).

In the intermittently submerged reactor process – utilizing, for example, round discs mounted on a rotatable axis – material exchange occurs as a result of alternating exposure of the growth surface to wastewater and air as the biofilm is subjected to continuous rotation (Fig. 20).

Figure 20. The intermittently submerged reactor process

In the activated-sludge process, development of the phase boundary required for adequate mass transport is facilitated either by surface aeration or volume aeration [142], [143]. In the case of surface aeration the wastewater is sprayed in the form of fine droplets by means of aggregates rotating horizontally or vertically at the water surface (Fig. 21). Volume aeration relies instead on fine gas bubbles produced in the aeration zone by an appropriate gas-introduction system. With volume aeration it is necessary to take into account as well the phenomenon of coalescence in the course of oxygen transfer [144]. Depending on the wastewater composition, finely dispersed gas bubbles may be stabilized, but they might also coalesce and immediately form large bubbles. Under coalescence-promoting conditions, aeration with fine bubbles should therefore be avoided in the interest of saving energy.

Figure 21. A surface-aeration facility

Only in a few exceptional cases is oxygen transfer accomplished outside the bioreactor in a separate aeration chamber. This approach is applicable to biofilters designed for upward flow

and operated either as fixed or fluidized beds (e.g., the Oxitron process).

Supplying necessary oxygen to the microorganisms via oxygen-containing compounds presents no particular problems. Nitrate need not be added specifically for this purpose: it is either already present in the wastewater, or is formed by ammonium oxidation (nitrification). Nitrate is deliberately converted to other forms through denitrification in the interest of nitrogen removal.

The use of hydrogen peroxide is of essentially no practical significance. However, if H_2O_2 were to be introduced it would be important to adequately condition the organisms so that they would form enough catalase for enzymatic cleavage of the otherwise bacteriotoxic hydrogen peroxide.

Mixing. Mutual contact between the three reaction partners bacteria, substrate, and dissolved oxygen is established automatically in the course of oxygen transfer, because the process inevitably produces considerable turbulence in the aqueous phase. Only in denitrification, which proceeds with the exclusion of oxygen, is there a need for special mixing of the water – sludge mixture – with the aid of a mixer or through injection of an inert gas (which can be recirculated if necessary).

Carbon, Nitrogen, and Phosphorus Elimination. Biological treatment of wastewater eliminates not only organic substances (measured as BOD, COD, or total organic carbon, TOC), but also nitrogen and phosphorus compounds. The oxidative degradation of organic compounds by heterotrophic organisms causes the organic matter to be mineralized to CO_2, NH_4^+, and PO_4^{3-}, with concurrent formation of bacterial mass.

Two different metabolic processes are involved in nitrogen removal:

1) Nitrification, which occurs with autotrophic organisms under oxic conditions

$$NH_4^+ + 2\,O_2 \rightarrow NO_3^- + H_2O + 2\,H^+$$

2) Denitrification, observed with heterotrophic organisms in the anoxic range in the presence of readily biodegradable organic compounds (e.g., acetic acid, methanol, etc.), assuming there is thorough mixing

$$6\,NO_3^- + 5\,CH_3OH \rightarrow 3\,N_2 + 6\,OH^- + 5\,CO_2 + 7\,H_2O$$

Heterotrophic organisms are responsible for phosphorus elimination, incorporating polyphosphate into their reserves under alternating anoxic – oxic conditions in a process known as "luxury uptake" [52].

Biotechnology makes it possible to combine these various elimination processes in a meaningful way provided appropriate attention is directed to the corresponding diversity in environmental prerequisites and growth characteristics, as illustrated in Table 4 for the case of the activated-sludge process.

Table 4. Essential conditions for bacterial metabolism and growth

Elimination process	Bacteria	Environ. conditions	Growth
Carbon	heterotrophic	oxic	rapid
Nitrogen			
Nitrification	autotrophic	oxic	slow
Denitrification	heterotrophic	anoxic	rapid in the presence of a carbon source
Phosphorus	heterotrophic	anoxic/oxic	dependent upon carbon elimination

Figure 22. Single-step carbon elimination
Q = wastewater; Q_{RS} = recycled sludge

Figure 23. Two-step carbon elimination
Q_1, Q_2 = wastewater streams; Q_{RS1}, Q_{RS2} = recycled sludge streams

Carbon Elimination. The biological elimination of carbon may take place as a single step, in

the form of a cascade, or as two steps, each with its own discrete sludge cycle.

The one-step approach (Fig. 22) is normally preferred under low-load biological conditions. The two-step mode of operation is usually conducted as a combination of a high-load first step with a low-load second step. In order to stabilize the second step (i.e., ensure sufficient sludge growth), the wastewater stream is sometimes split, with a portion of it being fed directly into the second stage (step feeding) (Fig. 23) [145]. In the cascade mode of operation (Fig. 24), utilized only in special cases, a second stream of wastewater can be fed directly into the second cascade.

Figure 24. Cascade system for carbon elimination
Q_1, Q_2 = wastewater streams; Q_{RS} = recycled sludge

Figure 25. Three-step elimination of carbon and nitrogen
Q = wastewater stream; Q_{RS1}, Q_{RS2}, Q_{RS3} = recycled sludge streams; C=carbon-elimination; N=nitrification; DN = denitrification

Nitrogen Elimination. The elimination of nitrogen is based on two different processes: nitrification (N), the oxidative conversion of ammonium ion to nitrate by autotrophic organisms, and denitrification (DN), the reduction of nitrate to molecular nitrogen by heterotrophic organisms in the presence of easily biodegradable organic compounds, as described above.

Wastewater is usually contaminated primarily by organic compounds, which must also be eliminated biologically, so the nitrogen-elimination process can be extended to cover the elimination of both carbon and nitrogen. This can be accomplished, for example, in a three-stage plant with three separate sludge cycles (Fig. 25). The last step must be conducted as a cascade, because adequate anoxic denitrification requires that an appropriate source of carbon be introduced in excess. Unreacted residue must than be degraded oxically.

However, this particular biotechnological approach to the problem entails a major capital investment coupled with high operating costs, so less costly solutions are being sought. For example, efforts have been made to achieve carbon elimination and nitrification in a single stage. For this purpose, the stage in question should be subjected to the lowest load level possible, permitting adjustment of the growth of heterotrophic organisms by a shift into the death phase, thereby establishing a proper match with the slow growth of the autotrophic organisms. This is essential to ensure that there will be no change in the sludge composition accompanying the withdrawal of excess sludge. Excessive growth or loss of various organisms through washing must be prevented to the greatest extent possible. This in turn imposes a demand for a larger bioreactor to ensure concurrent carbon elimination and nitrification, but at the same time eliminates the need for a third sludge-separating system (Fig. 26).

Figure 26. Two-step elimination of carbon and simultaneous nitrogen
Q = wastewater stream; Q_{RS1}, Q_{RS2} = recycled sludge streams; C = carbon-elimination step; N = nitrification; DN = denitrification

Here, too, an external source of carbon must be introduced for denitrification. In the absence of adequate amounts of low-nitrogen wastewater it becomes necessary to resort to a substance like methanol, which obviously increases the operating costs (see the first example in Section 2.1.4.3). The demand for methanol can be minimized or even eliminated by introducing a denitrification step prior to the first stage of joint carbon elimination and nitrification. Such a process combination can be operated either as two

steps with separate sludge cycles (Fig. 27) or as a cascade (Fig. 28), requiring only a final clarification. After nitrification, the nitrate that is to be eliminated is sent back for denitrification along with the recycled sludge (Q_{RS}), and/or introduced into the cascade first stage via recirculation (Q_{RC}) or backpass (Q_{BP}).

Figure 27. Two-step simultaneous elimination of carbon and nitrogen (nitrification) preceded by denitrification
Q = wastewater stream; Q_{RS1}, Q_{RS2} = recycled sludge streams; Q_{BP} = wastewater backpass; C = carbon elimination; N = nitrification; DN = denitrification

Figure 28. Cascade arrangement for carbon and nitrogen elimination preceded by denitrification
Q = wastewater stream; Q_{RS} = recycled sludge stream; Q_{BP} = wastewater backpass; Q_{RC} = recirculated wastewater; C = carbon elimination; N = nitrification; DN = denitrification

The potential extent of nitrogen elimination depends on the amount of nitrate returned, as well as on the carbon source available for denitrification [146]. A preceding denitrification step leads inevitably to unloading, and thus stabilization of the subsequent process of joint carbon elimination and nitrification.

Should the nitrogen elimination achieved in a preceding denitrification step prove insufficient, a second denitrification can still be imposed subsequent to carbon elimination and nitrification. Introduction of a suitable carbon source is again required in the form of a nitrogen-free wastewater stream or perhaps a stoichiometric excess of methanol. For this reason, final denitrification must take the form of a cascade so that any excess of the carbon source present at the end of the process chain will be eliminated biologically (Fig. 29) [147].

Figure 29. Two-stage cascade for simultaneous elimination of carbon and nitrogen, with denitrification both before and after
Q = wastewater stream; Q_{RS1}, Q_{RS2} = recycled sludge stream; Q_{RC} = recirculated wastewater; C = carbon-elimination step; N = nitrification; DN 1, DN 2 = denitrifications

Phosphorus Elimination. Biological phosphorus elimination accomplished in conjunction with chemical precipitation is found today primarily in the treatment of municipal sewage. The change from an anoxic to an oxic state, required for luxury uptake, is achieved by providing a preceding anoxic stage. Insofar as possible, reintroduction of dissolved oxygen or nitrate is avoided in this step, because every oxygen donor leads to a decrease in performance [52]. The desired end is met by a very high rate of recirculation (Q_{RC}) (Fig. 30).

Figure 30. Cascade arrangement for the elimination of carbon, nitrogen, and phosphorus, where in volumetric terms $Q_{\mathrm{RC}} \gg Q_{\mathrm{RS}}$
Q = wastewater stream; Q_{RS} = recycled sludge stream; Q_{RC} = recirculated wastewater; C = carbon-elimination step; N = nitrification; DN = denitrification; P = phosphorus elimination

2.1.3. Technology and Operation of a Wastewater-Treatment Plant

The central wastewater-treatment plant of a direct-discharge system can be subdivided into the following process segments [148]:

1) Feed
2) Chemical purification (e.g., neutralization)
3) Mechanical purification
4) Quantity and quality adjustment by means of buffer and balancing volumes
5) Separate detection of unusual influents in the catch volumes
6) Single- or multistep biological wastewater treatment, together with any necessary off-gas treatment
7) Sludge treatment and targeted disposal [149]
8) Discharge into a receiving stream, with appropriate account taken of potential high-water situations

Assessment of the individual process stages and selection from among possible process variants requires a precise knowledge of the particular wastewater situation in question (district wastewater register, wastewater regime, possible production-related variations as a consequence of economic factors and production mode), as well as a consideration of local circumstances.

The hydraulic dimensioning of the individual process sections constituting the treatment plant must be based on short-term maximum influxes of wastewater (m^3/s). However, likely increments such as those that would accompany a heavy rain dare not be neglected in the course of planning. Possible compensating measures within the plant itself can be considered for the successive stages assuming adequate equalization and buffer volumes will always be available.

In terms of sizing the various load-based process steps (e.g., the biological steps) it is the maximal influx in t/d that is decisive, taking into account the possible need for compensation on a daily or weekly basis. The actual goal of the process is also important: whether the plant is designed only for carbon elimination or for the elimination of both carbon and nitrogen.

The task of any central wastewater-treatment plant is to fulfill at all times the legal requirements stipulated in the corresponding official discharge license. For this reason, heavy emphasis must be placed on process reliability [150] in the individual processing steps. A disruption in one part of the plant (e.g., in the event of repairs) should not present a risk to the overall disposal function. Therefore, depending on its size, a wastewater-treatment plant should be designed and constructed as a two – stream or even better as a multistream operation. In order to detect weak points and define the requisite redundancies it has been found useful to conduct an *availability analysis*. This must in turn be based on the requirement that safe operation of the wastewater-treatment facility will be possible at all times.

In addition to quantity-oriented factors (volumetric flow rate, load), the quality of the incoming wastewater is also important in the dimensioning of a wastewater-treatment plant. In many cases, use of data acquired from other wastewater-treatment facilities is possible only to a limited extent. Wastewater qualities from different companies and different manufacturing sites vary tremendously due to differences in factors related to production, process design, and process integration. For this reason the relevant parameters must always be taken from experiments conducted at the laboratory and pilot-plant levels. It is thus understandable that wastewater-treatment plants associated with chemical operations differ greatly from one to another. Each must be custom-designed to suit the wastewater conditions at a particular location consistent with current state-of-the-art technology. For this reason several different plants are described in detail in Section 2.1.4 as a way of illustrating the potential diversity.

Buffer, Equalizing, and Receiving Volumes. To ensure that required effluent levels are reliably maintained, a biological wastewater-treatment plant should be operated insofar as possible without major quantitative or qualitative fluctuations in the inflowing wastewater. Buffering the production against short-term (daily) and long-term (weekly) variations imposes the need for equalization volumes. This buffering can be achieved in a decentralized way at the various production sites or centrally in the wastewater-treatment plant. The appropriate capacity is a function of the anticipated fluctuations. Figure 31 illustrates a typical buffering

Figure 31. Buffering strategy for dealing with a variable wastewater flow

strategy that takes into account inflow, utilization of the available volume, and loading of the subsequent biological stages from the standpoint of quantitative equalization over the period of one week. In practice, however, this approach is eclipsed by qualitative considerations.

Figure 32. Concentration-change patterns for biological wastewater purification
(A) Trickling filter with plug flow; (B) Activated-sludge process, total mixing
c_0 = influent concentration; c_1 = effluent concentration

Controlling unusual influxes into the wastewater-treatment plant, such as those resulting from an operational failure or fire, creates the need for centralized or decentralized receiving volumes. Their capacity depends in turn on the extent of the hazard potential. Of great importance with respect to the operation of a barrier system of this type is timely detection of an unusual event [151] with the aid of both analytical and organizational measures.

Biological Wastewater Treatment. Biological treatment of wastewater in the chemical industry usually takes the form of an activated-sludge process, in exceptional cases a trickling-filter process. Deciding which of these to implement requires consideration of two primary factors, the advantages and disadvantages of which are immediately apparent:

1) The activated-sludge process is conducted either oxically for carbon elimination and nitrification, or anoxically for the purpose of denitrification and phosphorus removal. The operating conditions are therefore predetermined. On the other hand, in the biofilm of a trickling filter (see Fig. 19), the oxic conditions at the surface are supplemented by anoxic or even anaerobic conditions in the interior, depending on the film thickness. Thus, it is likely that methane will be generated in an aerated trickling filter, perhaps even in large quantity.

2) In a trickling filter, wastewater (diluted, if necessary) flows via the return flow Q_R (see Fig. 19) through a packed column according to the principle of plug flow. This results in formation of a concentration gradient over the height of the trickling filter. Microorganisms at the top of the trickling filter come into contact with high concentrations of contaminants, which may inhibit degradation depending on the quality of the wastewater. On the other hand, if an activated-sludge process is operated as a thoroughly mixed system (see Fig. 15), the influent concentration C_0 is diluted immediately to the effluent concentration C_1, reducing the sensitivity of the system to toxic influents (Fig. 32).

Dimensioning of the biological stage of a wastewater-treatment plant for the chemical industry should be based preferentially on results from laboratory- and pilot-scale experiments. Sizing data from "comparable" treatment plants or municipal sewage-treatment plants can be used as a rough guide, but special account must be taken of the effects of low degradability and inhibition of the degradation process by substances that might be toxic at ambient concentrations.

The proper sizing of a trickling filter [152] depends for biological degradation on the load, expressed in terms of the loading rate per unit area (kg BOD or COD/$m^2 \times d$), and from a hydraulic standpoint on the washing efficiency (with return flow Q_R, if necessary) to prevent plugging and ensure elutriation of excess biomass.

The sizing of an activated-sludge plant [153] is based on the load expressed as the loading rate ("food") per unit volume [F/V = kg BOD (COD)/$m^3 \times d$] or, better still, on the sludge loading [food/microbe ratio F/M = kg BOD (COD)/kg STS$\times$d], where sludge total solids (STS) takes into account the sludge properties as well (see Table 5). The hydraulic aspect depends on the throughput efficiency [superficial velocity, $m^3/m^3 \cdot h = m/h$] of the external biomass separation as a function of the sludge properties [154], [155]. The design can reflect either sedimentation or flotation [155], [137].

Only the organic portion of the sludge parameters should be factored into the dimensioning of an activated-sludge plant. This is significant, especially in the case of simultaneous phosphorus precipitation, because considerable amounts of iron or aluminum phosphates accumulate in the activated sludge. In exceptional cases, simultaneous phosphorus precipitation may even prevent nitrification, because the nitrifying bacteria are unable to multiply to a sufficient extent (see Nitrogen elimination in Section 2.1.2).

Special Process-Engineering Solutions. Odor emission accompanying start-up of a wastewater-treatment plant has frequently been described, and it is regarded as a significant nuisance by residents in the immediate vicinity. The main components of the problem are quality, plant size, technology, and the location of the facility. Odor emission may be attributed to two causes:

1) Formation of aerosols during the aeration process, which acquire their odor only after evaporation.
2) Stripping of malodorous substances in the course of oxygen transfer, a process that competes with sorption (Fig. 33).

Figure 33. Mass transport at the gas – water and water – bacteria interfaces
DO = dissolved oxygen; DCO_2 = dissolved carbon dioxide

The solution to this problem is to build closed wastewater-treatment plants that retain the aerosols, simultaneously minimizing the quantity of off-gas through optimal oxygen utilization [10], [154]. This in turn opens the way to targeted off-gas treatment.

The Unox Process. The Union Carbide Corporation (UCC) has developed in the United States an activated-sludge process (Unox) based on the use of technical-grade oxygen. It consists of a closed cascade in which wastewater and gas flow in cocurrent fashion to ensure optimal uti-lization of the oxygen. Gas dispersal is accomplished with aeration mixers. The biological stage is followed by sedimentation (Fig. 34) [138], [157–159].

Table 5. Sizing of the activated sludge process for domestic sewage

Parameter	Loading rate per unit volume		Sludge loading		Activated sludge concentration (total solids), g/L	Sludge age, d
Treatment goal	kg BOD_5 / $m^3 \cdot d$	kg COD / $m^3 \cdot d$	kg BOD / kg STS · d	kg COD / kg STS · d		
Carbon elimination	<1	<2	ca. 0.3	ca. 0.6	3	ca. 5
Carbon elimination and nitrification	<0.5	<1	<0.15	<0.3	3	>10
Carbon elimination, nitrification, and aerobic sludge stabilization	<0.2	<0.4	<0.05	<0.1	4	>20

Figure 34. The Unox process
Q = wastewater stream; Q_{RS} = recycled sludge

Figure 35. The ICI deep-shaft process
Q = wastewater stream; Q_{RS} = recycled sludge

The Deep-Shaft Process [160]. The British concern ICI is credited with developing the deep-shaft process. This is based on a loop reactor with a depth as great as 200 m (Fig. 35), which is aerated with fine air bubbles during downward flow. At the high pressures characterizing the lower region, both oxygen and nitrogen are completely dissolved. The pressure drop accompanying subsequent upward flow causes gas bubbles once again to form, and this in turn serves both as the driving force for the loop reactor and as the basis for sludge separation by dissolved-air flotation.

Bayer Tower Biology (Turmbiologie) Process [7], [10], [161–163]. The Turmbiologie process was developed by the German company Bayer. This utilizes a bubble column associated with a head of water corresponding to as much as ca. 30 m. Aeration is provided by fine bubbles created with injectors distributed across the bottom. Any off-gases that accumulate are monitored and specifically diverted. These gases may in turn be fed into an appropriate treatment plant as required. Sludge separation is accomplished through sedimentation, or else by gassing or degassing flotation. Prior sedimentation the water – sludge mixture is deliberately degassed and flocculated in cyclones. Sedimentation occurs in Dortmund tanks placed either next to the reactor or around the upper portion of the bioreactor in the form of a collar (Fig. 36).

The Tall Bioreactor [163], [164]. Another German company, Hoechst, developed what is known as the Biohochreaktor ("tall bioreactor"). This is a loop reactor with a water column of ca. 20 m. Oxygen is introduced via radial jets installed below the internal flue. Sludge separation is accomplished by sedimentation in clarifiers, which are integrated into the upper portion of the bioreactor. The possibility of flotation is also under discussion (Fig. 37).

Figure 36. The Bayer biotower (Turmbiologie) process

Figure 37. The Hoechst tall bioreactor (Biohochreaktor) process

PACT Process [165–167]. The Powdered Activated Carbon Technology (PACT) process was developed in the United States by DuPont. In this approach to biological wastewater treatment, powdered activated carbon is introduced directly into the activated-sludge process. It has been shown that odor emission caused by stripping can in this way be reduced, and that the sludge properties are influenced positively as well. The resulting sludge becomes more dense, leading to a lower sludge volume. The space – time yield is thus improved, because there is more bacterial mass present in the activation system, and the sludge loading is reduced. The same effect can be achieved with other growth surfaces, including lignite – coke dust [168] and plastics. For economic reasons, the use of activated carbon is potentially significant only in cases where stabilization of the biological system is achieved through the selective adsorption of degradation-inhibiting wastewater components (see also Section 5.1.7.1).

Reliable Operation of a Wastewater-Treatment Plant. Apart from careful planning of a wastewater-treatment plant and a concern for redundancy in the design, it is necessary that provision also be made for specific monitoring and balancing of the individual stages and their reliable control [169]. Proper operation of a wastewater-treatment plant demands constant surveillance and the targeted adjustment of various process parameters. Adherance to the terms of a discharge license [150], [151] depends upon both the proper mode of operation for the wastewater-treatment plant itself and the quality of the inflowing wastewater. Monitoring of the relevant parameters can be accomplished through on-line measurements that facilitate direct intervention and control, or analytical results derived from wastewater samples, which reflect longer-term trends and are also essential for monitoring and documentation purposes. On-line measurements are available for parameters such as the following: quantity of wastewater (Q_R), temperature, pH, electrical conductivity, bacterial toxicity [170], [171], DO, density and/or solids content, TOC, total nitrogen, NH_4^+, NO_3^-, and total phosphorus and PO_4^{3-}.

Both the needs with respect to on-line measurements and the availability of suitable equipment for the purpose must be analyzed separately for every contemplated application. A survey of possible measurements and analyses applicable to the various process stages associated with a wastewater-treatment plant is provided in Table 6. Specific requirements may vary in individual cases.

2.1.4. Examples of Industrial Wastewater-Treatment Plants Based on a Variety of Centralized Processes

Differences in product spectra, differently configured production systems, and unique local conditions determine the nature of the water

regime associated with a particular chemical manufacturing plant.

Most such plants are "direct dischargers," i.e., they themselves operate centralized wastewater-treatment facilities and then discharge the purified effluent into the appropriate watercourse, taking into account the terms of an official discharge permit.

Some are indirect dischargers, releasing their wastewater – subsequent to applying decentralilzed treatment measures, complete with appropriate safeguards – into a public wastewater-disposal facility for further purification. The quality requirements pertaining to these wastewaters are established on the basis of widely accepted guidelines for indirect discharge together with local statutes.

The descriptions provided here of a number of different wastewater regimes, each with its own specific technical features, should illustrate the wide variety of possible solutions to the effluent problem. The plant technologies selected for presentation were determined on the basis of the quantity and contamination level of the waste-water, local conditions, and the technology available at the time of construction. Every waste-disposal plant is tailored to fit a specific application. The plants associated with direct dischargers have been further classified from a biotechnological perspective into

1) Single- and multistage activated-sludge plants
2) Oxygen plants
3) Plants with selective carbon and nitrogen elimination
4) Trickling-filter plants
5) Biofilter plants

2.1.4.1. Single-Stage and Multistage Activated-Sludge Plants

The Wastewater-Treatment Plant of BASF at Ludwigshafen, Germany [172–175]. The wastewater-treatment facility of BASF Aktiengesellschaft (Fig. 38) processes wastewater derived from the 350 production plants located in the city of Ludwigshafen and the neighboring communities of Frankenthal and Bobenheim/Roxheim. The industrial component makes up about 90 % of both the wastewater volume and the organic pollution load. In dry weather the daily influx may be as great as 700 000 m^3, with a maximum BOD_5 load of 375 000 kg. The facility removes 97 % of the BOD, 89 % of the COD, and 98 % of the nitrate.

Figure 38. Aerial view of the BASF AG wastewater-treatment plant at Ludwigshafen, Germany

The industrial wastewaters are first neutralized by introducing milk of lime (a calcium hydroxide suspension) into the main sewer (Fig. 39). After passing a coarse screening facility that retains bulky material, the wastewater is delivered by a pumping station (b) through two pressurized lines via a fine screen (c) into four circular primary clarification tanks (d). At this point, because of a short retention time (20 min), only rapidly sedimenting solids are separated.

A second section of the activated-sludge step consists of five activated-sludge "carrousel tanks" operated in parallel, with a total capacity of 300 000 m^3. These are outfitted with 110 surface aerators for supplying oxygen, which alone consume in the course of an hour as much as 15 000 kW of electrical power. The activated-sludge tanks are completely covered with glass-fiber reinforced plastic elements to minimize odor emission.

In addition to the degradation of organic matter, a degradation of nitrates introduced with the raw water also occurs in the activated-sludge unit. To ensure denitrification, one section of the circulation-tank system is kept oxygen-free, such that microorganisms there utilize oxygen from the nitrates for respiration. Consumption of roughly 50 t/d of nitrate in this way leads to a significant saving in the power demand for aeration.

The secondary clarification system (e) consists of 15 circular tanks with horizontal liquid

Figure 39. Schematic diagram of the BASF Ludwigshafen wastewater-treatment plant

flow and a total capacity $>100\,000\,m^3$. After the sludge has settled out in the secondary clarification system the purified wastewater flows into the Rhine. At high-water periods in the absence of a natural gradient for outflow, a wastewater pumping station (f) is capable of discharging $\leq 14\,m^3/s$ with a discharge head of 8 m.

A sludge pumping station (g) feeds most of the sedimented activated sludge back from the secondary settling tanks into the aeration tanks. A portion of the activated sludge – the so-called excess sludge – is sluiced out together with the primary sludge for sludge treatment.

The BASF wastewater-treatment plant has a central safety system for capturing toxic and poorly degradable batches of wastewater as well as water released for fire protection. The entire inflow can be led into two special aeration tanks as required, which serve as buffer volumes. A storage tank is also available for wastewater-buffering purposes. This tank is equipped with a special treatment system in which the wastewater can also be purified with activated carbon, for example. The overall storage capacity at the BASF wastewater-treatment plant amounts to $180\,000\,m^3$.

Excess sludge and primary sludge, which accumulates to the extent of $30\,000\,m^3$ per day containing up to 320 t of solids, emerges from the sludge-pumping station into thickening tanks (h). Here about 77 % of the sludge water separates by gravitational compression. After the addition of coal slurry, ash, and polymeric flocculants the concentrated sludge is subsequently dewatered in chamber filter presses (i) at pressures ≤ 15 bar to a moist-solid filter cake containing about 45 % solids.

The coal introduced into the clarifier sludge as a filter aid provides fuel for subsequent incineration. Five fluidized-bed furnaces (m) are capable of burning up to 1000 t of filter cake daily to carbon dioxide and ash. Organic constituents of the sludge decompose completely at a furnace temperature of ca. 1000°C.

The heat generated during incineration is used in waste-heat boilers (j) for steam production, air preheating, and boiler-feed preheating. The steam supplies a two-stage turbine (k) which generates 14 MW of electric power (l), provides

heat for the wastewater-treatment plant, and also supplies a portion of Ludwigshafen with domestic heat. In this way, clarification sludge serves to replace valuable sources of primary energy at many different points.

Figure 40. Aerial view of the Bayer AG wastewater-treatment plant at Leverkusen, Germany

Off-gases are dedusted in electrostatic filters (p) prior to further purification in wet scrubbers and subsequent stack discharge to the atmosphere. Resulting ash is used both in mining and as a reinforcing material at the BASF Flotzgrün landfill. A part of the ash is also recycled as a filter aid during dewatering of the clarification sludge.

The Wastewater-Treatment Plant of Bayer AG at Leverkusen, Germany [176], [177]. The Leverkusen wastewater-treatment plant is used for combined biological cleaning of the production wastewater from Bayer together with municipal wastewater from the lower Wuppertal catchment area (Fig. 40). The plant was erected in two stages: the first stage with open aeration tanks came into operation in 1971, and the second, which includes four biological towers (Bayer Turmbiologie), in 1980. Design parameters are as follows, with data applicable in 1995 in parenthesis:

Influent

a) Production wastewater 90 000 (67 000) m^3/d, BOD_5 load 95 (55) t/d
b) Municipal wastewater 70 000 m^3/d, BOD_5 load 14 t/d

Figure 41. Schematic overview of the Bayer Leverkusen wastewater-treatment plant

Primary clarification. Surface loading $1.0\,m^3/(m^{-2}\cdot h^{-1})$, retention time 2.5 h

6 Buffer tanks. Usable volume $3\times10\,000\,m^3$, $1\times15\,000\,m^3$, $2\times25\,000\,m^3$

4 Biotowers (tower biology). Usable volume $4\times13\,000\,m^3$, water height 26 m, retention time 14.5 h, oxygen feed 4×30 t/d, food/volume ratio 1.8 kg $BOD_5 m^{-3}\,d^{-1}$, food/microbe ratio 0.32 kg BOD_5/kg solids · d

Intermediate clarification. Surface loading (superficial velocity) $0.95\,m^3$, retention time 7 h

2 Biotanks. Usable volume 11 500 and $25\,000\,m^3$, water depth 3.5 m, retention times 3.4 and 7.5 h, oxygen feed 60 t/d, food/ volume ratio 0.8 – 1.7 $BOD_5\,m^{-3}\,d^{-1}$, food/microbe ratio 0.32 kg BOD_5/kg solids · d

Secondary treatment (rectangular clarifier). Surface loading (superficial velocity) $0.8\,m^3$, retention time 3 h

Final clarification (Dortmund tank). Surface loading $1.1\,m^3$, retention time 6.3 h

Wastewater entering the treatment plant by gravity flow (induced by a 10-m drop from the production facilities) is neutralized (d) after passage through a screen, lifted with centrifugal pumps, and then sent through a primary clarification system (e) equipped with chain-driven scrapers (Fig. 41). The mechanically cleaned, neutral wastewater is then homogenized in buffer tanks (f) with respect to the production-dependent parameters quantity and pollutant load. It is also possible here to introduce municipal wastewater for dilution purposes in the interest of optimal operation of the tower biology.

Wastewater is pumped from the buffer tanks directly into the biotower (g). Oxygen is fed through injectors arranged on the tank bottom. In order to optimize the oxygen-transfer efficiency, a constant volume of water is admitted to the injectors from a separate pumping circuit. Wastewater treated in the towers in the first process step flows via degassing cyclones into the elevated intermediate settling system (h), where activated sludge and water are separated. Recycle sludge is returned to the biotowers. Air required for the activation process is obtained from the production plant through a separate pressure line. Off-gases from the buffer tanks and biotowers are thermally deodorized in an off-gas treatment plant. All sections of the plant are covered to prevent odor emissions.

Figure 42. Various types of settling tanks
A) Rectangular flat tank, equipped with flight scraper; B) Circular flat tank, equipped with a bottom scraper; C) Hopper-bottom ("Dortmund") tank; a) Inverted buffle; b) Flight scraper; c) Bottom scraper

Effluent water from the intermediate biotower clarification process is treated further together with preclarified municipal wastewater from the Wupper Regional Authority in biotanks (i) from the first stage of construction in the form of a second processing step. Conventional surface aerators (j) supply the necessary oxygen to the aeration tanks. The available rectangular clarifiers (k) and a series of "Dortmund tanks" (l) (see Fig. 42 C) serve for the final clarification.

Three different sludges arise during the course of this wastewater purification, and all three are disposed of as follows:

1) Neutralization of primary sludge together with municipal primary sludge and excess sludge are introduced into a thickener where they are thickened with the aid of a polymeric additive to a level of 7 % solids.
2) The thickened mixed sludge is conditioned with lime and an iron salt solution and dewatered by means of chamber filter presses to ca. 65 % residual moisture.
3) The resulting filter cake is incinerated in a multiple-hearth furnace, and the ash formed is deposited in a nearby landfill.

Figure 43. Aerial view of the Hoechst AG wastewater-treatment plant at Frankfurt-Höchst, Germany

The Central Wastewater-Treatment Plant of Hoechst AG at Höchst, Germany [178], [179]. The central wastewater-treatment plant of the Hoechst at Höchst (Fig. 43) comprises three phases of construction, the first of which was brought into operation in 1967. The overall capacity of the plant is 160 t/d of BOD_5. Only industrial wastewater is treated in this plant, supplied via a special sewerage network 50 km in length. Separate systems are available for dealing with cooling water and rainwater on one hand, and sanitary sewage on the other.

Industrial wastewater flows into the treatment plant under gravity, reaching the neutralization tank after passing through a coarse screen. The predominantly acidic wastewater is neutralized with milk of lime, which is metered in through a mixing conduit in the sewer ahead of the neutralization tank. A flocculating agent ($FeSO_4$ solution) is then added to flocculate finely-divided insoluble constituents.

Wastewater pumps lift the neutralized wastewater to the surface from a depth of about 10 m. After flowing through a sand filter the water passes a fine screen and enters the presedimentation tanks of the individual purification stages, flocculation aids being added to improve sedimentation. Sludge separated in the primary settling tanks is discharged and pumped into thickener units for further concentration.

The chemically and mechanically pretreated wastewater, which is largely free of solids, is pumped into a safety and equalizing tank with a volume of 40 000 m^3, one-half of which is used to buffer the concentration and pollutant levels while the other half is kept in reserve for use in the case of a major disruption.

Subsequent to this buffering the wastewater enters an aeration tank where dissolved organic matter is eliminated by microorganisms. The biological part of the first phase of the plant is equipped with two such tanks, each with a depth of 3.6 m operating on the basis of surface aerators. This stage is at present not in operation. The activated-sludge section of the second phase, with a depth of 8.3 m, occupies considerably less space, has five rectangular tanks, and employs radial-flow nozzles for aeration. The third phase (Fig. 44) utilizes two tall bioreactors (Biohochreaktor; d and e). The concentrically arranged circular aeration space with external sedimentation tanks (f) has a water height of 20 m, and is equipped, like the second expansion stage, with radial-flow nozzles. Seven guide tubes installed above the nozzles cause the tank to function as a loop reactor. A perforated plate separates the upper region of the reactor, providing a stilling and degasification zone.

Compared with the conventional approach to construction, the tall bioreactor (Biohochreak-

Figure 44. Schematic overview of the third development phase of the Hoechst central wastewater-treatment facility

tor) offers the following important advantages (see Section 2.1.3):

1) Improved introduction of oxygen as a result of the radial-flow nozzles and the great depth of the water.
2) Less off-gas because of the low oxygen requirement.
3) Reduced space demands as a result of compactness.
4) Optimum monitoring of leaks.

Excess sludge together with primary sludge is conditioned with calcium hydroxide and dewatered with membrane filter presses. After storage in bunkers the filter cake – containing >40 % solids – was formerly deposited in a controlled landfill. After 1994 a sludge-incineration plant assumed responsibility for disposal of the filter cake.

The neutralization facility as well as the primary clarification tanks in the second and third stages are encased, as are all aeration tanks.

The Wastewater-Treatment Plant of Hoechst AG at Griesheim, Germany [180], [181]. The wastewater-treatment plant at the Griesheim works of Hoechst Aktiengesellschaft is designed for a daily BOD_5 load of 5 t, and treats industrial wastewater containing a particularly wide range of difficultly degradable and intensely odorous materials. Noteworthy features of the plant are the fact that activated carbon is added to the activated-sludge process and that all the off-gases with their accompanying volatile materials are drawn off from the various tanks to prevent odor emission. The activated carbon improves the biological efficiency of the plant as a result of its adsorption characteristics, and it stabilizes the biological system. Conceptually this plant, illustrated in Figure 45, represents a third stage in the expansion of the Hoechst wastewater facilities.

Figure 45. Aerial view of the Hoechst AG wastewater-treatment plant at Frankfurt-Griesheim, Germany

Process wastewater entering through a main sewer is first subjected to a neutralization and precipitation step, followed by a primary clarification for the separation of solids. The liquid is then collected in an equalizing tank 25 m high with a storage capacity adequate to accommodate all the wastewater collected in a single day. In the inlet section of the activated-sludge plant the raw water is diluted with cooling water, and fine-grain activated carbon is added (20 – 100 g per cubic meter of influent). The secondary wastewater-treatment stage consists of two tall bioreactors (Biohochreaktor) 24 m high, each with an aerated volume of 8000 m^3. The tanks for both the aeration stage and the integrated secondary clarification are constructed of steel, protected by several coats of isocyanate-based paint. The tall bioreactors operate on

the basis of a sludge consisting of activated carbon and biomass at a concentration of 10 – 20 kg of solids per cubic meter of aerated volume. Sludges obtained from primary clarification and the tall bioreactor are concentrated separately in two thickening units. The primary sludge is dewatered with centrifuges and the reactor sludge with chamber filter presses. This dewatered sludge is stored in bunkers prior to further treatment. To avoid problems with odor, all parts of the plant exposed to raw water, including the tall bioreactors and thickeners, are enclosed. Off-gases are removed by suction and incinerated in a combustion chamber, which operates as a separate unit within the sludge-incineration plant. Deodorization is assured by incineration with gas and fresh air at 900°C.

The incineration plant consists of an incineration furnace, a combustion chamber, and appropriate auxiliary facilities. Here the sludge is incinerated in a fluidized-bed furnace at a temperature >900°C. Natural gas is injected as a supplementary fuel, along with fresh air (preheated in a flue-gas recuperator). A cyclone is used to separate the ash, while the remaining residues are precipitated in a venturi scrubber. Hydrogen chloride and sulfur dioxide are absorbed here simultaneously by the addition of aqueous alkali. The sludge water is returned to the treatment plant, whereas ash goes to a landfill.

Wastewater Treatment of Hüls AG at the Marl Works, Germany [182–185]. The 120 different plants associated with Hüls in a closely integrated system at the Marl site produce about 2.8×10^6 t of saleable products annually. The product range includes, among others, basic and speciality chemicals, performance products, thermoplastics, and rubber, along with polymeric materials. The nearby Lippe is a rather small river, and that places heavy demands with respect to the water management of a large chemical processing operation. It has been necessary from the outset to collect all wastewater separately from unpolluted cooling and rainwater, and to process it in a wastewater-treatment plant incorporating state-of-the-art technology. For this purpose roughly 32 km of wastewater collecting sewers are embedded in roads passing through the plant.

Wastewater-Treatment Facilities. Mining operations play an important role in the runoff conditions at the 6.5 km^2 plant site, and it proved necessary to construct two mechano-biological wastewater-treatment plants at the outflow of the wastewater sewer system. These facilities purify all the polluted process wastewater arising from the production processes, amounting to ca. 77 000 m^3/d.

The wastewater treatment facilities have been expanded as production has increased, and consist now of a screening plant, a wastewater pumping station, a mechanical primary-clarification facility, two-step neutralization, an activated-sludge plant (the first biological step), mechanical secondary purification, and a settling pond (the second biological step), as shown in Figure 46.

From the standpoint of capacity these treatment facilities would be sufficient to meet the domestic sewage demands of a city of about 800 000 inhabitants. The activated-sludge plants are designed for a low food/microbe ratio ($\leq$0.1 kg BOD/kg of activated sludge solids per day), and to operate with nitrification. The nitrogen content of the plant effluent does not exceed 5 mg of ammonium nitrogen per liter. Each of the four large aeration tanks constituting the first biological stage has a volume of 6000 m^3, and is equipped with four surface aerators.

Experiments associated with the planning process indicated that short-term concentration changes would be without detrimental consequences if the wastewater is mixed rapidly with all the other water already present in the tank. Given the high hydraulic efficiency of the installed aerators, the tank contents circulate completely within 2 min. Moreover, as a result of the high activated-sludge concentration in the aeration tanks (6 – 8 kg of activated-sludge solids per cubic meter), concentration peaks are buffered by adsorption onto activated sludge flocs. Reaching these high activated-sludge concentrations required allocating to each aeration tank two humus tanks, operated with a surface-loading rate $\leq$0.5 m/h.

The clarified sludges (both primary sludge and excess activated sludge from the two wastewater-treatment plants) are collected in gravity thickeners and pre-dewatered. This thickened sludge, when mixed with organic polyelectrolytes, coagulated and passed over filterpress

belts, yields a filter cake with a solids content of 20 – 30 %. The dewatered, clarified sludges are incinerated in a fluidized-bed furnace (Fig. 46), in which the energy deficit is balanced out by a combination of solid fuels and natural gas.

Selective purification of split wastewater streams at the production plants has led to an annual decline in the load reaching the central wastewater-treatment facility and the River Lippe (Fig. 47). The range of split-stream treatments applied extends from sedimentation with and without coagulation, via stripping, to thermal wastewater treatment. The central wastewater-treatment facilities essentially perform the function of downstream purification of a mixed wastewater, as well as monitoring discharges into the Lippe. COD concentrations in the treatment-plant effluents are currently (1995) below 75 mg/L, and the corresponding BOD_5 concentrations below 10 mg/L. Beyond that, various steps have been taken in the production sphere to reduce the quantity of wastewater generated. In the period 1989 – 1995 alone the hydraulic load on the wastewater-treatment plants fell by more than 20 %.

The quality of the water discharged into the Lippe is checked continuously on the basis of extensive analyses conducted in specially equipped laboratories.

Safety Features. Apart from the wastewater, the two collecting mains for cooling and rainwater are monitored continuously as well. Here there is also continuous control of the corresponding water quality.

In the event of a remote control-panel indication that the cooling water has become contaminated, quick-acting conduit slide valves stop all discharges into the Lippe within one minute, and pumps deliver the water instead into large reservoirs. Two reservoirs, each with a capacity of 25 000 m^3, are available in the vicinity of each of the treatment plants, providing a total stor-

Figure 47. Product-based loading of the River Lippe from Hüls

DOC = Dissolved organic carbon.

age volume of 100 000 m^3. Another function of the storage systems is to protect the wastewater-treatment plants from extreme loads that could place the biological treatment steps in jeopardy or prevent the self-set purification goals from being met. Intensive area-wide monitoring of the sewer system in the plant complex and automated analytical monitoring of the wastewater-treatment plant influents ensures rapid detection of unusual loads (e.g., due to organic materials), permitting the influent to the wastewater-treatment facilities to be diverted as necessary with the aid of pumps into the reservoirs. At the conclusion of each such storage event the water collected is analyzed and then purified in accordance with the analytical results.

The Merck Wastewater-Treatment Plant at Darmstadt, Germany. The central wastewater-treatment facility at the Merck headquarters in Darmstadt (Fig. 48) was designed for a maximum BOD_5-removal capacity of 30 t/d, and it processes a daily average of 12 500 m^3 of wastewater with a BOD_5 of 12 t. Included in these figures is the domestic sewage (3 vol %) generated by the approximately 8000 employees, rainwater (7 vol %), and cooling water (30 vol %).

Figure 48. Plan of the Merck wastewater-treatment facility at Darmstadt
a) Retention basins 1 – 4; b) Presedimentation; c) Polishing pond; d) Secondary clarifiers 1 – 3; e) Sludge treatment; f) Equalizing tank; g) Tall bioreactor; h) Biological tanks 1 and 2

A unique feature of this wastewater-treatment facility, devoted exclusively to wastewaters from the plant complex, is the fact that it must process wastewaters derived from an unusually varied spectrum of production processes related to numerous organic and inorganic chemicals and pharmaceuticals, usually prepared on a batchwise basis. As a result of this typical polyproduction operation, there are large fluctuations over time in the quantity of wastewater collected along with the pollutant load, the pH level, and other significant characteristics. An additional challenge is presented by the relatively weak receiving stream and, related to that, the requirements and targets associated with the quality of effluent released from the wastewater-treatment plant.

Fluctuations due to polyproduction are damped in the case of COD and BOD_5 by a relatively uniform load from a production facility that operates continuously throughout the year, and by a long retention time of 5 d with intensive wastewater mixing in the equalizing tank (f), the biological stage (g), and the polishing pond (c).

In-plant wastewater-pretreatment facilities are used to keep most heavy metals, haloorganic compounds, and difficultly biodegradable materials away from the central wastewater-treatment plant, and in some cases to convert them to degradable materials. Surpluses of ammonium nitrogen and phosphate in the various wastewaters are temporarily stored, and at times of nitrogen or phosphorus shortage they are fed as nutrient solutions to the wastewater-treatment plant itself or distributed to other consumers.

As a result of in-plant pretreatment (hydrolysis) of difficultly biodegradable materials it has become possible to increase the COD-removal rate in the wastewater-treatment plant to 92 %. In the case of BOD_5, 99.5 % degradation is achieved.

Effluent concentrations expressed in terms of the most important parameters averaged (at the end of 1993): COD 120 mg/L, $BOD_5 < 10$ mg/L, adsorbable organic halogen compounds (AOX) 0.3 mg/L, inorganic nitrogen 5 mg/L, total phosphorus 2 mg/L, and heavy metals and fish toxicity equal to or below threshold values established by the German water-pollution control act. Daphnia, algae, and luminescent bacteria generally survive under the standardized test conditions in wastewater that has been diluted 1: 1. Attempts are being made to reduce the phosphorus content by simultaneous precipitation.

In order to provide for the retention of water used for fire fighting, wastewater contaminated by plant breakdowns, or extreme amounts of rainwater, four retention basins (with capacities of 1000 m^3, 3000 m^3, 8000 m^3, and 11 000 m^3) are available at the wastewater-treatment plant itself (a), and there is an additional basin (5600 m^3) located at the production plant as well. There is also the 10 000 m^3 equalizing tank (f) that is on average only half full, and this too can be used for the separate collection of contaminated wastewater.

Wastewater collected in a combined sewer system is treated based on the following steps (Fig. 49): coarse screening (a), grit chamber (b), neutralization with hydrochloric acid or lime (c), primary settling in a 1500-m^3 tank (d), equalization (e), optionally either one- or two-step biological treatment in a tall bioreactor (f; first stage; Hoechst system; 9000 m^3, of which 5000 m^3 is aerated volume and 4000 m^3 is for final sedimentation) and a biotank (g; second stage: Lurgi system; 2 tanks, each with aerated volumes of 7500 m^3 and the possibility for selective nitrification and denitrification), final sedimentation (h; three tanks, each 2100 m^3), and aerated pond polishing (i; 20 000 m^3). Based on a parallel mode of operation in the biological step, the average loading rate per unit volume is 0.6 kg BOD_5 m^{-3} d^{-1}, and the sludge loading fluctuates between 0.1 and 0.2 kg BOD_5 per kg solids per day as a function of the sludge properties (index 40 – 150 mL/g) and sludge concentrations (3 – 6 g solids/L) prevailing in the activation. In both steps, aerobic treatment consistent with the activated-sludge process is accomplished with compressed-air aeration.

Sludge formed in the course of wastewater purification (0.6 t/d of primary sludge solids, 3.5 t/d of excess activated sludge solids, corresponding to 0.3 kg of solids per kilogram of BOD_5 removal), together with excess sludge from a branch plant (ca. 1.4 t/d of solids) is thickened in two 800 m^3 thickeners from a level of ca. 5 g/L in the recycled sludge to a solid content of ca. 30 g/L. The thickened sludge is either conditioned with iron(III) chloride and lime [$Ca(OH)_2$] and dewatered in two chamber filter presses to a solid content of about 35 %, or

Figure 49. Schematic diagram of the Merck wastewater-treatment plant

dried after organic conditioning (with polyelectrolytes) and dewatering (decanter).

The dewatered (ca. 25 t/d) or dried (6 t/d) clarification sludge is utilized externally insofar as possible either as a material or as a fuel, or else it is deposited in a landfill. The contaminant load in this clarification sludge is comparable to that of a good municipal sludge, and falls well below all limiting values specified in the German ordinance on sewage sludge.

Additional very small amounts of residue are generated as screenings (0.02 t/d, external incineration), grit-chamber material (ca. 0.4 t/d, landfill), and floating sludge from the primary settling tanks (ca. 0.05 t/d, external incineration).

The wastewater-treatment plant is active and under the supervision of operating personnel around the clock, 365 days per year. Selfmonitoring is assured by numerous continuous online instruments and analysis in the company laboratory, which is staffed on a daily basis.

2.1.4.2. Oxygen-Based Facilities

The Bayer Wastewater-Treatment Plant at Wuppertal-Rutenbeck, Germany [186]. The Wuppertal-Rutenbeck wastewater-treatment plant was built to dispose of wastewater originating from the Elberfeld Works of Bayer AG (see Fig. 50). It was first put in operation in the spring of 1977.

Figure 50. Aerial view of the Bayer AG wastewater-treatment plant at Elberfeld, Germany

Construction of this facility, which for reasons of space was necessarily located in Wuppertal-Rutenbeck, downstream from the production facility, demanded a compact design due to space limitations, as well as the laying of a sewer within a tunnel ca. 1 km in length.

The biological segment of the wastewater-treatment plant was intended to operate in two stages, both based on the oxygen process. Thus, instead of air, 98 % oxygen was to be injected from injectors as a way of supplying the activated sludge with sufficient oxygen for aerobic metabolism. Small quantities of off-gas discharged deliberately from the enclosed plant were deodorized in a thermal off-gas treatment plant.

A large reduction in the amounts of both pollutant and water has in the meantime been achieved by decentralized means at the produc-

tion plants themselves. As a result, aeration by oxygen is now necessary only in the first aeration stage, with normal air being used in the second. Off-gas incineration previously required has been dispensed with as well, since there are no longer any offensive odors.

Wastewater collected within the Elberfeld Works is fed to the Rutenbeck plant (Fig. 51) through a sewer leading to the influent pumping station (a). Compatibility of the wastewater with activated sludge present in the plant is checked continuously with a respirometer, and the measurements are transmitted to a control room where they are recorded.

Centrifugal pumps force wastewater from the inlet structure via two buffer tanks (c) and a subsequent neutralization facility into the first aeration stage (b). The quantity and extent of the organic load are continuously measured and recorded in the control room. This in turn permits centralized control of the entire plant by a process computer, ensuring that the activated sludge always receives an organic pollutant load that is as constant as possible, corresponding to optimum purification efficiency at all times. Load fluctuations can be levelled out with the aid of the buffer tanks. Appropriate nutrient solutions can be added to correct the carbon: nitrogen: phosphorus ratio in the wastewater as a way of optimizing the efficiency of biological degradation. Fluctuations of the influent pH are levelled out by neutralization.

The first aeration stage (b) consists of two separate trains, each with a volume of 6000 m^3 and divided into three cascades, one of 1500 m^3 and two of 750 m^3. The oxygen content of the gas phase in these two systems is >50 %. Return sludge is introduced into the first of the cascades (f). Injectors (e) installed in several rows on the tank bottom ensure very intensive aeration with oxygen, simultaneously guaranteeing thorough mixing of the reactor contents. Approximately 94 % of the organic constituents are removed from the wastewater in this very first stage.

The first aeration stage is followed by intermediate settling (i), in which activated sludge separates by sedimentation from the partially purified wastewater. Flocculation cyclones (d) to improve the settling properties of the activated sludge are installed between the aeration stages and the associated intermediate settlers or secondary clarifiers.

Sedimented sludge is pumped back into the aeration tank (b) in the form of recycle sludge, whereas excess sludge is conveyed off for sludge treatment.

Wastewater from the intermediate settler is transferred to the second aeration stage (g) which, as noted above, is oxygenated with air. This stage also incorporates two trains, each with a total volume of 1600 m^3 consisting of two cascades of 800 m^3. The second stage is designed to eliminate slowly degraded materials that have passed through the first stage. The activated sludge is separated in a subsequent secondary clarifier (k) and pumped back into the second stage as return sludge, or removed as excess sludge for sludge treatment.

Overall BOD_5 elimination is >99 %, and COD elimination amounts to 96 %. As a result of altered wastewater composition, increased retention time, and increased sludge age it has now become possible to pursue nitrification in the second aeration stage as well.

Until 1991, excess sludge was dewatered in decanters (j) to a solids content of ca. 15 %, and granulated in a mill dryer to a granular powder, which was then discarded in a landfill. With a reduction in the amount of sludge produced this process became uneconomical, so now the sludge is dewatered only to the extent of ca. 11 % dry matter, and the decanter discharge is processed further at another wastewater-treatment plant.

Both aeration stages incorporate simultaneous precipitation for phosphorus removal, whereby the phosphate is precipitated by metal salt solutions and removed together with the excess sludge.

The Wastewater-Treatment Plant of Knoll AG at the Minden Works, Germany [187]. The wastewater-treatment plant illustrated in Figure 52 began operating in 1980. It differs from conventional plants mainly in the fact that the activated sludge is aerated with technical-grade oxygen rather than air.

Mixed wastewater arriving from the production facility (process and cooling water from the manufacture of pharmaceuticals, sanitary water, and surface water, totalling about 8000 m^3/d) is pumped first into the mixing and equalizing tanks (b), with volumes of 8000 and 10 000 m^3, respectively. Their function is primarily that of

equilibrating the wastewater with respect to both constituents and pH, and of ensuring throttled inflow to the biological stage during production-free periods (weekends, public holidays).

The wastewater is then transported via a two-stage neutralization plant (c), in which milk of lime can be introduced to raise the pH, to the primary settling facility (d). Here, in a covered rectangular tank (volume 510 m^3), readily settleable materials are separated.

The mechanically cleaned wastewater is then delivered to the heart of the plant: the biological treatment stage. This consists of four enclosed circular tanks (h), all equal in size, through which the water passes successively. Because of the high oxygen demand in the first tank, it is here that the oxygen is introduced (e). Gas and the water – sludge mixture flow in cocurrent fashion through the subsequent stages. The oxygen content of off-gas from the final stage is 40 %.

The aerated volume can be varied between 4200 and 5100 m^3 by adjusting an overflow weir in the effluent shaft after the fourth stage. Gas is introduced through jet nozzles.

The water/sludge mixture then flows through two circular secondary clarifiers (i; each with a volume of 2500 m^3), in which sludge is once again separated by sedimentation. The biologically treated wastewater ultimately enters the Weser River via a penstock.

Part of the settled sludge is returned to the first aeration tank, while the remainder is transported as excess sludge to the thickener (f). Sludge obtained in the primary settling tank is thickened in an analogous way.

The sludge, to which flocculation aids have been added, is dewatered with membrane chamber filter presses (g) and fed to a landfill.

The extent of contaminant elimination based on the change in BOD_5 is ca. 98 % (90 % based on COD). Because of a shortage of phosphorus in the original wastewater, this nutrient is introduced directly in the form of phosphoric acid.

There are a number of advantages that result from aerating the activated sludge with technical-grade oxygen instead of air. Thus, the amount of off-gas requiring attention is definitely less than from air-driven plants, thereby virtually eliminating odor nuisances in the surroundings. The oxygen transfer per unit time is also greater, and the required aeration volume and therefore the land requirement turns out to be smaller as well. One important advantage associated with the four-stage cascade system is great adaptability of the biomass to fluctuations in loading. These advantages are partly offset by the need for an oxygen supply (with the attendant costs), and the added expense of installing the necessary safety equipment.

Wastewater-Treatment System of Bayer Corporation (Miles, Inc. before April 1, 1995), Agricultural Chemicals Division, at Kansas City, Missouri, USA. The Kansas City pesticide production facility of Bayer Corporation protects surface waters in the Missouri River with the aid of its terminal wastewater-treatment operations (Fig. 53). The system selected was the Unox process biological system, which utilizes high-purity oxygen rather than air. This system was chosen in preference to an air-fed system because the oxygen-enriched biological system is enclosed, thereby reducing odors and minimizing size constraints, and such a system need be only 20 % as large as a typical air-fed aerobic reactor.

All process wastewaters from the site, together with storm and rain waters, enter the primary clarifiers (d) for solids removal (Fig. 54). The wastewater is then pumped through overhead lines to the equlization system prior to secondary treatment. Two equalization tanks (f), 11 355 m^3 each, are piped in such a way that either tank can be operated in the lead or lag position; moreover, each tank can be isolated should a spill or a high level of pesticides mandate additional hydrolysis time.

The bioreactors (h) are of the Unox design, consisting of two parallel three-stage reaction trains. Each reactor has a capacity of 511 m^3. Pure oxygen is added to the first stage of each train, and the off-gas from the final stage is vented. Return activated sludge is recycled from the first final clarifier. Surface aerators in each bioreactor are used to completely mix the biomass. Typical operating parameters for the biosystem are listed in Table 7.

Oxygen for the bioreaction is produced in an air separation plant with an output capacity of 45 400 kg/d. Byproduct nitrogen vapor from this plant is piped to all operating units for use as an inert gas.

The two final clarifiers (i; 1836 m^3 each) are operated in series for solids removal. Return activated sludge from the first clarifier is split between the two reaction trains, and the second clarifier operates in a sludge-wasting mode. When solids inventories rise above the allowable operating level, sludge wasting is commenced from the lead clarifier.

Final clarifier effluent is pumped through two parallel carbon adsorbers (k) for tertiary treatment. Tertiary treatment by carbon absorption was selected because of carbon's great affinity for high molecular mass hydrocarbons. Such compounds tend to be nonbiodegradable, or at least not totally eliminated by biodegradation. Tertiary treatment has also been found to reduce toxic properties of the effluent with respect to aquatic life. Prior to installation of the tertiary plant, LC_{50} fish toxicities averaged between 1: 3 and 1: 6. Subsequent to start-up of the tertiary plant this was reduced to between 1: 0 and 1: 2. The adsorbers operate in an up-flow expanded-bed mode. Spent carbon is pulsed on a time basis ○Bfrom the bottom of the adsorbers, while regenerated carbon is added to the tops of the adsorber beds. Each adsorber has a capacity of 136 080 kg of granular activated carbon.

Carbon is transported hydraulically through the adsorption system to the spent-carbon furnace for regeneration. The plant has a fluidized-bed regeneration furnace capable of regenerating 18 145 kg/d of carbon. This furnace is designed with two beds, an upper bed for drying the carbon and volatilizing light organics and a lower one for pyrolysis and reactivation. The regeneration system has an afterburner for oxidizing as much as possible of the organics, a

∗∗ Mixed liquor volatile suspended solids.

high-energy venturi for particulate removal, and a scrubber for the conversion of sulfur dioxide to sodium sulfite. Sulfite-to-sulfate conversion takes place in a liquid-phase oxidation tower that is shared with the plant's hazardous-waste incineration system.

Effluent from the treatment system is analyzed by means of a magnetic flowmeter and a suspended-solids monitor. A continuous-flow compositor samples the effluent prior to its discharge to surface waters.

All process vessels are covered and vented by means of induced draft to a central location prior to off-gas incineration as a way of minimizing odors.

Particularly noteworthy is the level of total dissolved solids (TDS) in the biofeed of this system: 3.2 %. The biomass has been acclimated to a high salt concentration, a precaution that exceeds standard practice. One other interesting facet of the operation is the high level of dissolved oxygen (DO) present in the system. It has been reported that high DO levels in an oxygen-enriched system result in a light floc with poor settling characteristics, but this is not consistent with experience gained from this particular system. The removal efficiencies for the system based on influent versus effluent levels are >99 % for pesticides and >90 % for BOD.

2.1.4.3. Treatment Facilities with Selective Carbon and Nitrogen Elimination

Wastewater Treatment of Bayer AG at the Dormagen Plant, Germany. The Dormagen production site covers about 6 km^2, and is divided by a railroad line. It is the home of ca. 50 chemical plants associated with Bayer and about 20 petrochemical plants of EC Erdölchemie GmbH, a 50 % subsidiary of Bayer. Wastewaters are discharged into two separate sewer systems. All wastewater from Bayer and EC Erdölchemie requiring special treatment is merged for processing purposes with industrial wastewaters from a neighboring sugar factory and a Dormagen brewery.

The first experimental wastewater-treatment plant at this location was erected by Erdölchemie in 1958. Mechanobiological wastewater treatment began in 1963, and by 1973 the facility had expanded to become the largest industrial wastewater-treatment plant at that time in all of Europe, with a purification capacity of 90 000 m^3/d. This was joined in 1978 by a second, completely covered wastewater-treatment plant in the Dormagen West Works, with a purification capacity of 25 000 m^3/d for the purification of intensely odorous wastewaters, mainly derived from the production of crop-protection agents.

Since then the amount of wastewater subject to treatment has continually been reduced, as has the pollutant load. For example, of the 63 t of COD originally generated daily by Bayer, 24 t/d was eliminated in 1991 directly at the production plants, leaving 34 t/d to be subsequently removed in the two centralized wastewater-treatment facilities, with the remaining 5 t/d being discharged. The total amount of wastewater fell at the same time to 58 000 m^3/d. Simultaneously, it became essential that new requirements be met for the reduction of nitrogen and phosphorus loads, necessitating the construction of production-integrated wastewater-treatment facilities together with additional treatment capacity. The fact that excess capacity was now available at the smaller of the two centralized

treatment plants because of diminishing wastewater volumes and loads presented an opportunity to develop an effective and low-cost solution, one which was realized in 1992.

The plan consisted of converting the wastewater-treatment plant at the West Works into a facility for the pretreatment of split streams for nitrogen- and phosphorus-containing waste, with conversion of the existing facility into a two-stage biological wastewater-treatment plant. For this purpose, two aeration tanks previously operated in parallel were reconfigured for connection in series, while two of the three existing Dortmund tanks originally intended for secondary treatment were allocated to the first aeration stage, the third being associated with the second aeration stage.

COD removal with simultaneous phosphate precipitation now takes place in the first stage, whereas the nitrification of ammonium ion (originally present or formed during first-stage treatment), via nitrite and nitrate, occurs in the second stage. These aerobic processes are carried out with the aid of the bacterial strains *Nitrosomas* and *Nitrobacter*, releasing both heat and H^+ ions. The biological treatment step is a sensitive one, and it demands effective control over both temperature and pH. The effluent from this primary treatment plant with its high nitrate load, together with the remaining wastewater, proceeds to the central treatment facility, where targeted denitrification is accomplished with the aid of a deliberately anoxic operation at the outset of the biological treatment. The two plants have also been separated organizationally. Because of the high sensitivity of the primary nitrification step, the primary treatment plant for nitrogen- and phosphorus-containing wastewaters must rely upon close cooperation with the relevant Bayer production facilities. The plant is therefore under the supervision of Bayer's environmental protection department. As before, the joint secondary treatment of all wastewater subject to obligatory treatment is accomplished under EC's guidance. The flow diagram in Figure 55 helps to explain the current mode of operation.

Both the primary treatment plant and the central facility are equipped with neutralization stages (a), holding tanks (b) for optional use, primary clarifiers (c), and two- or single-stage biological treatment based on the activated-sludge process and conducted in the aeration tanks (d) and the secondary clarifiers (e). Aeration is accomplished with the aid of injectors specially developed by Bayer, and secondary clarification is carried out in Dortmund tanks 16 m deep. Design data are as follows:

Primary Treatment Plant with Nitrification	
Wastewater flow	$8000\,m^3/d$
O_2-transfer capacity	30 t/d
COD influent	20 t/d
COD removal	17 t/d
Nitrification capacity	
(NO_3^--nitrogen)	2.8 t/d
Neutralization	
Volume	$760\,m^3$
Retention time	2.3 h
Holding tanks	
Volume	$9100\,m^3$
Primary clarification	
Volume	$3000\,m^3$
Retention time	9 h
Surface loading	$0.3\,m^3/(m^{-2}\cdot h^{-1})$
Aeration	
Volume	$5600\,m^3$
Retention time	17 h
Specific O_2 transfer	2.6 kg
Wastewater space loading	$1.4\,m^3\,m^{-2}\,d^{-1}$
Secondary clarification (aeration)	
Volume	$2000\,m^3$
Retention time	6 h
Surface loading	$1.1\,m^3/(m^{-2}\cdot h^{-1})$
Nitrification	
Volume	$5600\,m^3$
Retention time	17 h
Specific O_2 transfer	$2.6\,kg\,m^{-3}\,d^{-1}$
Wastewater space loading	$1.4\,m^3\,m^{-3}\,d^{-1}$
NH_4^+-nitrogen load	0.1 kg/kg solids · d
Secondary clarification, nitrification	
Volume	$4000\,m^3$
Retention time	12 h
Surface loading	$0.6\,m^3/(m^{-2}\cdot h^{-1})$
Off-gas (for incineration)	
Volume	$15\,000\,m^3/h$
Central Treatment Plant with Denitrification	
Wastewater flow	$80\,000\,m^3/d$
Max. O_2-transfer capacity	80 t/d
Nitrate-removal capacity	
(NO_3^--nitrogen)	4.3 t/d
COD influent	90 t/d
COD removal	75 t/d
Neutralization	
Volume	$960\,m^3$
Retention time	18 min
Holding tanks	
Volume	$4500\,m^3$
Primary clarification	
Volume	$8000\,m^3$
Retention time	2 h
Surface loading	$2.25\,m^3/(m^{-2}\cdot h^{-1})$
Aeration	
Volume	$32\,000\,m^3$

Retention time	12 h
Specific O_2 transfer	$2.5\,kg\,m^{-3}\,d^{-1}$
Wastewater space loading	$2.6\,m^3\,m^{-3}\,d^{-1}$
Sludge loading	0.6 kg BOD_5/kg solids · d
Sludge growth	0.3 kg solids/kg COD removal
Secondary clarification	
Volume	$18\,500\,m^3$
Retention time	6 h
Surface loading	$1\,m^3/(m^{-2}\cdot h^{-1})$

As a result of the various reconfiguration measures described, all requirements under German water legislation are met, including nitrogen and phosphate elimination.

Biological Wastewater-Treatment Plant of DEA Mineraloel AG at the UK Wesseling Facility, Germany [188–190]. The DEA Wesseling Works is a refinery and petrochemical complex with an annual crude-oil throughput of 6×10^6 t. The site is a direct discharger into the Rhine, and it must therefore meet the corresponding regulatory requirements for wastewater quality. The permissible inorganic nitrogen concentration (defined as the sum of all nitrogen from NH_4^+, NO_2^-, and NO_3^-) was previously 60 mg/L, which could be met with nitrogen removal at the 94 % level in the wastewater-treatment plant. As of 1 January 1995 the permissible value was reduced to 40 mg/L.

A modern five-stage wastewater-treatment plant based on the Bayer tower-biology principle became operational in 1981, replacing a single-stage aerobic plant of flat construction (Fig. 56). An average of $8000\,m^3$ of wastewater passes through daily, containing 6.5 t of BOD_5 (ca. 800 mg/L) and 8.1 t of NH_4^+ ion (ca. 1000 mg/L).

Figure 56. Aerial view of the DEA Mineraloel AG wastewater-treatment plant at Wesseling, Germany

In addition to contamination by hydrocarbons, wastewaters from the individual plants contain large amounts of nitrogen and sulfur in the form of NH_3 and H_2S, which enter the wastewater as a result of hydrocracking and refining of various crude-oil fractions. Separable oils are removed by phase separation in a coupled upstream physical purification stage. Stripping permits the H_2S level of the wastewater to be lowered to a maximum of 50 ppm. The stripped H_2S

is then converted to elemental sulfur by the Claus process (→ Sulfur, Chap. 6.).

The first of the five reaction stages in the biological treatment train (Fig. 57) is a denitrification (a), in which 80 % of the BOD_5 from the raw wastewater is degraded. To ensure anaerobic nitrate respiration, a nitrate-containing stream is recycled to this stage from the last nitrification stage. Gasification is accomplished with a mixture of the plant's own off-gas (N_2 and CO_2) and pure CO_2 withdrawn from the plant network. One important function of this treatment is protection of the subsequent nitrification from inhibitors present in the raw wastewater.

Nitrification is carried out in two stages, the first of which – activation with partial nitrification (c) – is a combination of aerobic degradation of the remaining BOD_5 and nitrification of 50 – 85 % of the ammonium nitrogen present. For removal of the remaining ammonium ion a nitrate-containing recycle stream flows from the outlet of the second nitrification stage (d) to the first denitrification (a_1). The two nitrification stages are aerated with air from a turbocompressor passing through a system of tubes on the reactor bottom that is outfitted with Bayer injector nozzles. The air requirement is 10 800 m^3/h at an oxygen utilization of 60 – 75 %. Nitrate is converted via nitrite to molecular nitrogen in the second denitrification stage (a_2), with methanol added as a carbon source.

The last activation stage (e) serves as protection against a BOD_5 breakthrough.

Wastewater flows through the entire plant under gravity, the water level falling from a height of 24 m at the first reactor to 17 m in the last secondary clarifier (f). All reaction stages are incorporated into closed tanks, with the intermediate and final clarifiers being Dortmund tanks.

After centrifugation, excess sludge is disposed of by incineration in a residue incinerator associated with the power station.

The Wolff Walsrode AG Wastewater-Treatment Plant at Bomlitz, Germany. The Bomlitz joint wastewater-treatment plant serving Wolff Walsrode and the community of Bomlitz was built in the years 1975 – 1977 at a cost of 7×10^6 €. It utilizes the principle of denitrification [191], and was one of the first industrial wastewater-treatment plants to incorporate this mode of operation.

As early as 1963 – 1968, extensive preliminary studies directed toward this end were carried out as a joint venture by Wolff Walsrode and the Institute for Community Water Management and Waste Engineering of the Technical University of Hannover. The objective was to test the so far undeveloped biological purification principle of denitrification as a way of utilizing as an oxygen source the nitrate content of wastewater derived from nitrocellulose production.

Preliminary experiments were initiated on a laboratory scale (total volume of the experimental plant, 53 L), pursued at pilot-plant scale (total volume 3.9 m^3), and completed with an industrial-scale facility (total volume 123 m^3). As a result, the potential for applying microbiological principles to a practical bioengineering process was substantiated, and dimensioning parameters were worked out for the design of a large plant [192], [193].

The most important findings in the course of this effort were:

1) Activated sludge from a municipal wastewater-treatment facility has already reached its full denitrification capability after only ten days. An operational change from anoxic denitrification to aeration (in the absence of nitrate) has no significant effect on contaminant-removal efficiency. The mode of operation can thus be changed as required.
2) The BOD_5 removal efficiency does not differ from that of a conventional activated-sludge plant.
3) The small amount of oxygen (<2 mg/L) introduced in the form of large bubbles during circulation of the activated sludge by aeration has no negative effect on denitrification.
4) The nitrate concentration falls and the alkalinity rises in proportion to the extent of BOD_5 removal.
5) A low phosphate content in industrial wastewater necessitates phosphate addition – to an average level of 3.7 g of phosphorus per kilogram of BOD_5.
6) Sludge flotation in the secondary clarifier due to the evolution of nitrogen gas can be avoided by brief, intensive aeration prior to secondary clarification.

Since at the same time an expansion of the municipal wastewater-treatment plant for the community of Bomlitz also was pending, it was

Figure 57. Schematic diagram of the DEA Mineraloel AG wastewater-treatment plant
a) Denitrification; b) Intermediate clarification; c) Activated-sludge treatment with partial nitrification; d) Nitrification; e) Activated-sludge treatment; f) Secondary clarification

decided to construct a "Bomlitz joint biological wastewater-treatment plant" outside the boundaries of the Wolff Walsrode production facility. The plan was based on the wastewater and pollutant loads indicated in Table 8.

Table 8. Projections utilized in planning the Bomlitz joint wastewater-treatment facility

	Wolff Walsrode	Municipal system	Overall projection
Wastewater flow, m^3/d	16 000	2 000 ∗	18 000
BOD_5 load, kg/d	8 000	465	8 720 ∗∗
Population equivalent	200 000	11 625	218 000

∗ Including rainwater from the municipal combined sewer system.
∗∗ Including 255 kg/d of BOD_5 from sludgefiltrate liquor.

The treatment plant become operational in 1978, and reached constant levels of purification by 1980. In the course of time the various removal percentages in the biological stage have stabilized themselves as follows:

BOD_5	97 %
COD	76 %
DOC ∗	73 %
Nitrate-nitrogen	95 %
Ammonium-nitrogen	95 %
Total nitrogen	73 %
AOX ∗∗	70 %

∗ DOC = dissolved organic carbon.
∗∗ AOX = adsorbable organic halogen compounds.

Not taken into account by these data are load reductions achieved as a result of in-plant avoidance and pretreatment measures.

Overall, the following advantages have become apparent in the denitrification process [194]:

1) Energy savings attained through the use of nitrate instead of atmospheric oxygen (7 W/m^3 of installed capacity during nitrate respiration instead of 47 W/m^3 during oxygen respiration).
2) An increase in acid-binding capacity as a result of alkalinity developed during denitrification (i.e., a saving in terms of neutralizing agents).
3) Little excess sludge production (ca. 0.5 g of solids per kilogram of BOD_5 eliminated).
4) Reduction in the nitrogen load of the receiving water.

The flow diagram in Figure 58 shows the individual steps in the wastewater-treatment process. Water from the local authority is mechanically preclarified at the treatment-plant site using a screen (a), a grit chamber (b), and a settling tank (c). This water is then mixed in the inlet structure with recycled sludge and wastewater from the production facility. The industrial wastewater is adjusted with milk of lime to pH 5 – 6 in a neutralization plant at the factory (which has been in operation since 1956), preclarified mechanically, and pumped to the inlet structure.

The activated-sludge plant consists of four circular tanks (d) connected as a cascade, each 20 m in diameter, 6.2 m deep, and with 1800 m^3 of usable capacity. Thus, including the interme-

diate aeration section, ca. 8000 m^3 of total reaction volume is available. During the denitrification phase, circulation is achieved as a result of large bubbles introduced through a perforated tubular grid on the tank bottom. In aerobic operation the required input of air is ensured by injectors producing fine bubbles.

Intermediate aeration is essential for stripping nitrogen-saturated wastewater from the activation step down to the solubility limit of nitrogen relative to air. An aeration tank (e) with a capacity of 350 m^3 guarantees an aeration time of only 10 min even at peak load. A coupled hydrocyclone located downstream is used for degasification as well, but also for agglomeration of the sludge flocs. Defoaming agents or coagulation aids can also be introduced at this point.

The first secondary clarifier stage consists of two circular tanks (f) connected in parallel, each 38 m in diameter and with a surface area of 1000 m^2 and a capacity of 3600 m^3. In order to minimize the floating of activated sludge, suction dredges for the rapid conveyance of recycle sludge together with skimming troughs for clearing away any floating sludge have been installed on the scraper bridge.

A further secondary clarifier stage consists of a third secondary clarifier (h) connected to another intermediate aeration unit (g) of the same design as those used in the first stage. Clarified wastewater enters the receiving stream (the Bomlitz) via a step cascade (i) in which it is enriched with oxygen.

The return-sludge pumping station (j) includes four pumps, permitting operation with a reflux ratio >100 %. Excess sludge from the biological step is thickened together with primary sludge from the municipal sedimentation tank, conditioned with lime, and dewatered with chamber filter presses (k) to 40 – 45 % solids; the resulting "bio-lime" is subsequently used in agriculture.

Even today this operation still meets all the standards of the most recent wastewater legislation. Nevertheless, because of the largely anoxic

mode of operation the purification capacity with respect to ammonium is no longer sufficient to cover the increased demand, given the nature of the available receiving stream. Trials were therefore conducted in 1987 with a pilot-scale plant (total volume 6.4 m^3) aimed at additional nitrification. The results form the basis for a plan for increasing the efficiency of the joint facility. The proposal envisions introducing into the circuit (upstream) a mixing and equalizing volume of 16 000 m^3 capacity with a variable fill level as a way of smoothing out fluctuations in quantity and load over the course of the week, together with a second holding tank (n) with a constant fill of 5000 m^3. Feed and discharge to the aeration tank will be controlled via a new pumping station (l).

In addition to a smoothing-out in the quality and quantity of influent water and the resulting constant operating mode in the plant, the additional volumetric capacity should make it possible to conduct an at least partial nitrification operation in the existing activation cascade.

2.1.4.4. Trickling-Filter Facilities

Wastewater-Treatment Plant of Hoffmann-La Roche AG at Grenzach-Wyhlen, Germany. The plant utilizes large-scale equipment to prepare not only a wide range of pharmaceutical speciality products but also vitamins. This leads to as much as 200 000 m^3/d of cooling water and 8000 m^3 of wastewater contaminated with organic chemicals.

Separation of the Wastewater Streams. Individual wastewater streams are maintained in 3 separate sewage systems with a total length of 5 km as follows:

1) Wastewater heavily contaminated with organic material but containing only small amounts of inorganic salts and traces of organic solvents and acids (chemical wastewater 1).
2) Wastewater contaminated mainly with inorganic chemicals but containing some organic contaminants, as well as strongly acidic wastewaters (chemical wastewater 2).
3) Cooling water that has been strictly confined to closed circuits for the purpose of removing heat from chemical processes, and is chemically uncontaminated.

The first two streams described are fed to the biological wastewater-treatment plant, where they undergo appropriate treatment depending upon the specific nature of the contaminants (Fig. 59).

The plant is dimensioned in terms of the following capacities:

Chemical wastewater flow	8400 m^3/d
COD load	46 t/d
BOD_5 load	27 t/d

Neutralization. The weakly acidic "chemical wastewater 1" is first adjusted to pH 7 by neutralization (a) with aqueous sodium hydroxide.

Primary Sedimentation. Suspended matter is next removed in a primary sedimentation unit (b). The suspended matter consists essentially of all the activated carbon consumed in the production plant. The presence of this activated carbon makes it possible to take advantage of two positive effects: the carbon adsorbs pollutants up to the point of 100 % saturation, and it also acts as a welcome filter aid when the resulting sludge is later dewatered in a chamber filter press. In order to reduce fluctuations in concentration and quantity, "chemical wastewater 1" is led after primary sedimentation into a 15 000 m^3 buffer tank (c).

Subsequent biological treatment consists of two steps, one utilizing a trickling filter and the other an activated-sludge system.

Trickling Filter, Biological Stage I. The first partial purification by biological means is carried out in a trickling filter (d) with a usable volume of 2250 m^3. The water is passed over plastic fittings (Hydropak) with a specific surface area of 200 m^2/m^3. This stage is capable of removing 30–50 % of the BOD_5 load depending on the level of contamination. The requisite oxygen is derived from air circulating at the rate of 24 000 m^3/h, with a fresh-air component of 8000 m^3/h. Any solvents that do not undergo decomposition are simultaneously blown out and removed from the exhaust air by means of an activated-carbon adsorber system (e). The enclosed character of the construction in combination with this adsorption facility guarantees the absence of odors. Because of the short retention time of the water in the trickling filter, the most easily degradable materials are the ones

Figure 59. The Hoffmann – La Roche AG wastewater-treatment plant at Grenzach-Wyhlen, Germany

mainly removed at this stage, which has a positive effect on sludge quality in the subsequent aeration stage.

The trickling-filter effluent is mixed with the acidic "chemical wastewater 2," which is characterized by a light organic load and is supplied from a second 5000 m^3 buffer tank, as a way of smoothing out fluctuations in concentration.

Activated-Sludge Plant, Biological Stage II. The second biological stage comprises three aeration units connected in parallel, over which the combined wastewater is distributed. One of these units is a flat aeration basin (f) constructed of concrete with a water depth of 4.4 m and a usable volume of ca. 3000 m^3. Oxygen is introduced by means of submerged aeration. The other two aeration units are identical closed steel tanks (g), each with a water depth of 20.3 m and a usable volume of 6300 m^3. Oxygen introduction is via injectors. Liquid from the tanks is recirculated to serve as a propellant for these nozzles. The propellant pumps are switched on and off in a cyclical fashion as a way of controlling the nitrification and denitrification processes.

Four turboblowers (h) generate the required compressed air. Because of differing water depths, single-stage blowers are used for the aeration tanks and two-stage blowers for the aeration basins. The blower output is adjusted as a function of the oxygen demand in the corresponding biological process.

Secondary Clarification, Sludge Dewatering, and Sludge Incineration. Each of the three aeration units is associated with its own secondary clarifier (i). Settled sludge is collected with chain-driven scrapers or suction dredges, and then pumped to two mutually independent thickeners, where it is thickened to a solids content of 2 – 6 %.

After conditioning with iron chloride and lime, the thickened sludge is dewatered in chamber filter presses (k) to a solids content of 40 – 45 %. In this form its heat of combustion is 3700 kJ/kg.

The dewatered clarified sludge is incinerated in a multiple-hearth furnace (m) with a supporting flame of natural gas. The resulting ash can be disposed of in the same way as domestic refuse.

Exhaust-Air Treatment. All parts of the plant are either enclosed or covered to prevent odor problems. They are at all times kept under a slight underpressure by the application of suction. Exhaust air from the ventilators is purified via activated-carbon adsorbers or cross-flow washers.

The wastewater-treatment plant of the Hoechst AG Kalle-Albert Works at Wiesbaden, Germany, is designed for a wastewater flow of up to 20 000 m^3/d, with an influent organic BOD_5 load of up to 33 t. The facility consists of a chemicomechanical stage, followed by two biological stages, with subsequent sludge treatment. The plant is laid out in two processing trains (Fig. 60).

The design of the plant is characterized by the removal of orthophosphate present in the influent through precipitation with slaked lime as well as nitrate denitrification in both the equalizing tank and the heavily loaded trickling filters incorporated as a subsequent stage.

Chemicomechanical Stage. The predominantly acidic wastewater reaches the inlet of the neutralization unit via a pumping station (a) that includes a screening system, and it is neutralized (b) with milk of lime. Alkaline peaks are balanced out with concentrated hydrochloric acid. The pH is adjusted to 8.5 as a way of precipitating out phosphate present in the influent. The inorganic sludge is separated along with primary sludge in the primary clarifiers (c).

Under normal operation this chemically and mechanically pretreated wastewater, which is largely free of solids, flows directly to the equalizing tank (d). Water that is abnormally heavily contaminated (e.g., water resulting from the extinguishing fire) is drained as necessary into a safety basin (e) to prevent possible harmful effects in the subsequent biological systems.

Biological Stages. Biological purification is accomplished in two stages. The first consists of two heavily loaded trickling filters (f). Trickling-filter effluent passes immediately into the two aeration tanks (h) that constitute the second stage. Nitrate present in the plant influent is denitrified to some extent in the equalizing tank of the chemicomechanical stage and in part in the two trickling filters of the first biological stage.

Sludge Treatment. Excess and primary sludges are combined and thickened (h), and after conditioning with iron salt and slaked lime the thickened mixed sludge is dewatered in filter presses (j).

Design specifications for the facility are as follows:

Figure 61. Schematic diagram of the Ciba Geigy AG wastewater-treatment plant at Münchwilen, Switzerland

Plant influent	
Wastewater flow	20 000 m^3/d
BOD_5 load	33 t/d of neutralization influent 30 t/d of influent to the biological stages
Trickling filters	
Space loading	2.8 kg BOD_5 m^{-3} d^{-1}
BOD_5 degradation	70 – 75 %
Aeration	Forced aeration via ventilators
Air flow	20 000 m^3/h, of which 10 000 m^3/h is fresh air and 10 000 m^3/h is recycled air
Exhaust air	Deodorized by thermal afterburning
Aeration basin	
Space loading	1.3 kg BOD_5 m^{-3} d^{-1}
Sludge loading	0.26 kg BOD_5/kg (dry solid matter) · d
BOD_5 degradation	90 – 95 %
Aeration	Diffused aeration via Hoechst radial-flow nozzles
Overall plant	
BOD_5 degradation	98 – 99 %
Specific excess sludge production	0.25 kg (dry solid matter)/kg BOD_5 degraded

2.1.4.5. Biofilter Systems

The Wastewater-Treatment Plant of the Ciba Geigy AG Agro-Development Center at Münchwilen, Switzerland [195–198]. This wastewater-treatment plant has been in operation since 1991. It is used exclusively for treating wastewater obtained during the development and small-scale production of organic intermediates and crop-protection agents. The flow of true process wastewater is about 15 m^3/d, to which must be added ca. 60 m^3/d of slightly contaminated wash water, for a total of ca. 75 m^3/d. Characteristic features of this wastewater are the presence of crop-protection agents at the level of a few mg/kg, organic compounds (in some cases as emulsions) in the range of a few grams per liter of total organic carbon, and occasionally a very high salt content (several tens of grams per liter). The design of the plant was based on the following parameters:

Wastewater flow	
Process water	15 m^3/d
Wash water	60 m^3/d
Total	75 m^3/d (ca. 20 000 m^3/a)
BOD	
Load (estimate for design purposes)	200 kg/d
Concentration	2700 mg/L
TOC	
Load	225 kg/d
Concentration (90 % degradable)	3000 mg/L
Refractory (for estimating the activated-carbon requirement)	300 mg/L
Activated-carbon requirement	
Design	3 kg/m^3
Observed	1 kg/m^3

Process water and wash water are collected in separate distribution systems and pumped to the treatment plant. The process wastewater is collected in a total of three 40-m^3 tanks. The tanks are equipped with mixing nozzles and interconnected in such a way that a relatively high

degree of homogeneity is achieved, equivalent to a quantitative and qualitative smoothing-out over the course of an entire week. The washwater is held temporarily in a 60-m^3 tank. An attempt is made by suitable mixing of the wastewaters to achieve the highest possible degree of constancy in the organic loading of the treatment plant, as well as relatively minor fluctuation in the salt concentration.

In the first treatment stage (see Fig. 61), solids and sludges already present in the wastewater, as well as those formed as a result of treatment, are removed by neutralization (a), flocculation (b), and sedimentation (see Fig. 61).

The second stage consists of three tower-form bioreactors (c) connected in series, which are filled with an orderly packing made of plastic. The liquid flows upward through the first reactor and downward through the others. Reactors 2 and 3 can also be operated in parallel. Microorganisms fixed to the plastic surfaces degrade roughly 90 % of the TOC and at least 98 % of the BOD. Fixing the bacteria in this way makes it easier to cope with a high salt content while at the same time facilitating long-term retention in the system of special slow-growing bacteria. The latter, by degrading more persistent substances, reduce the load remaining for the subsequent activated-carbon treatment.

Wastewater discharged from the bioreactors contains free-floating bacteria, and this is pumped via two parallel crosscurrent microfiltration units (d) in an attempt to remove as much of the solid matter as possible.

The wastewater is next passed over two activated-carbon adsorbers (e) connected in series, in which traces of nondegradable organics and crop-protection agents still present are removed by absorption.

The treated wastewater effluent is monitored (f) continuously by an on-line TOC analyzer. All other wastewater parameters, including levels of crop-protection agents, are determined in the laboratory on the basis of composite samples.

Once the adsorption capacity of the granular activated carbon has been exhausted the charge is thermally reactivated by the supplier.

The bioreactors are backwashed approximately once a week with purified wastewater. The resulting mixture of biological sludge and water is collected in a tank, and from there dosed continuously into the influent of the coagulation stage. The sludge obtained is thickened (h) and transported in this form to another chemical wastewater-treatment plant where it is dewatered with centrifuges and incinerated in a fluidized-bed furnace.

The treatment plant operates largely automatically seven days a week, although staff are present only on the five workdays during normal working hours. Labor input for operation of the plant (excluding analysis) amounts to roughly one-half of a full-time employee.

The following performance data refer to experience gained during the first year of plant operation:

Wastewater processed:	
Lightly laden (TOC 50 mg/L)	60 m^3/d
Heavily laden (TOC 2000 mg/L)	15 m^3/d
Total (TOC 1400 mg/L)	75 m^3/d
Critical substances present (concentration)	1 – 100 (30 – 50 mg/L)
Extent of removal:	
TOC	98 %
COD	99 %
Critical substances	>99 %

2.1.4.6. Indirect-Discharge Facilities

Optimization of Indirect Wastewater Discharge by Henkel KGaA at its Düsseldorf-Holthausen Works, Germany [199–201]. The firm, with its principal production facility at Düsseldorf, is a major indirect discharger of chemical wastewater. The plant site, including production facilities, laboratories, administration buildings, storage areas, and connecting routes, comprises a total paved area of ca. 10^6 m^2.

Structure of the Site Sewage System. Wastewaters and precipitation are drawn from the entire complex via a highly segmented drainage system ca. 70 km in length. This could be described as a combined sewer system designed according to standard specifications. True wastewater from production operations is in most cases pretreated at the place of origin prior to discharge into the plant sewage system. All processes employed are designed to meet code requirements and other official administrative regulations. Before discharge into the sewagetreatment plant of the city of Düsseldorf, all waste-

water is first accumulated in a central wastewater-treatment facility located outside the boundaries of the actual site, from which it is subsequently drained off continuously into the municipal sewage system. Total wastewater flow from the plant amounts to ca. 7×10^6 m^3/a, most of it production wastewater. This figure includes ca. 300 000 m^3 of sanitary wastewater and ca. 400 000 m^3 of rainwater. The daily COD discharge averages 32 t at a COD/BOD_5 ratio of ca. 2.

Structure and Function of the Central Wastewater-Treatment Facility. This plant (see Figs. 62 and 63), which first went into service in 1978 and was considerably expanded in the late 1980s, consists of a screw pumping station [Fig. 63 (e)] with a total capacity of 6100 m^3/h, a screen (f) for the removal of coarse materials, two identical 1200-m^3 mixing and equalizing tanks (i) with continuous flow that are equipped for both neutralization and grease removal, and an additional wastewater-storage basin (a) with a capacity of 4800 m^3. All units for conveying wastewater have odor-tight coverings of glass-fiber reinforced plastic panels. The plant is controlled largely automatically with the aid of a process computer.

Figure 62. Overview of the Henkel KGaA central wastewater-treatment facility at Düsseldorf, Germany

Under normal circumstances all the mixed wastewater is conveyed through one of the two U-shaped mixing and equalization tanks (i). A central trough distributor makes it possible to allocate the influent wastewater uniformly through six inflow openings into the available tank volume. Variability in retention time is used to ensure optimum mixing and equalization. Grease, oil, and other floating matter not completely removed by the stream-splitting operation separate on the water surface. These are extracted by a skimming device and conveyed into special floating-sludge collection tanks (h). After removal of residual water the sludge is transported as necessary with the aid of a gantry dredger system into transport containers for conditioning with sawdust and subsequent transfer to a waste-incineration plant.

Maintenance of the required pH range in the mixing and equalization tanks is assured by introduction of acid or alkali through an automatic neutralization system. At the bottom of these tanks is a propellant system driven with filtered wastewater, which generates a uniform degree of turbulence, thereby keeping precipitated material in a state of suspension. The fluid level in the tanks is automatically held constant by adjustable overflow weirs at the tank outlets.

In normal service the second mixing and equalizing tank and the wastewater-storage tank are not charged with wastewater, but are nonetheless maintained in a constant state of readiness. In the event of a disruption in wastewater flow, a fire, or some similar emergency threatening to produce highly contaminated and perhaps toxic wastewater, up to 6000 m^3 of influent can be accommodated in these two tanks (Fig. 62).

Wastewater from the production facility is monitored on a continuous basis, both in the sewer system and in the influent and effluent of the central wastewater-treatment plant. Control stations are equipped with on-line analytical instrumentation for continuous monitoring of the organic load (TOC), biochemical oxygen demand (BOD), potential toxicity (bacterial toximeter), conductivity, pH, and anionic surfactant content. Processing of the on-line measurements is attended to by a "wastewater-control expert system," which takes into account not only a scientific database, but also previous experience gained in the course of plant operation. This system is capable whenever necessary of independently activating empty tank units or sounding an alarm.

The "Sewage-Treatment Plant – South" Maintained by the City of Düsseldorf. Effluent from the Henkel wastewater-treatment plant is connected via the so-called Düsseldorf – South Main Sewer, which also drains the southern parts of the city, with the Düsseldorf – South

Figure 63. Schematic diagram of the Henkel wastewater-treatment facility
a) Storage basin (4800 m^3); b) Warehouse; c) Operations center; d) Tank farm; e) Wastewater lifting facility; f) Screening plant; g) Volume measurement; h) Floating-sludge tank; i) Flow-mixing tanks (1200 m^3 each)

sewage-treatment plant. The wastewater flow time from the Henkel delivery shaft to the municipal sewage-treatment plant is 3 – 4 h over a distance of ca. 8 km.

The sewage-treatment plant itself was designed as a typical single-stage mechanobiological plant, and it began operating in 1975. The dry-weather flow to this facility is roughly 100 000 m^3/d, with a daily COD load of 106 t. Therefore, from a volume standpoint the impact of wastewater from the Henkel works amounts to only about 18 %, but ca. 30 % based on pollutant load. One screw pumping station (consisting of 8 segments) supplies the plant with a maximum of 23 m^3/s of wastewater from which undissolved and mineral constituents are removed with the aid of coarse and fine screens and two circular degritters. A primary clarification stage (27 400 m^3) is followed by a biological-treatment stage (23 800 m^3) fed at a maximum rate of 2.85 m^3/s, into which air is introduced by surface aerators.

Since 1992, the final sedimentation unit (surface area 15 120 m^2, depth 2.70 m) has been accompanied downstream by a contact filtration plant (24 chambers with a capacity of 60 m^2 each, filter height 2 m), in which the concentration of total phosphorus in the treatment-plant effluent is constantly maintained below 1 mg/L by the addition of precipitants.

Because of increasingly stringent legal requirements applicable to the purification performance of the plant (e.g., Appendix 1 of the German Wastewater Administration Guidlines, size class 5) as well as factors related to sewage technology in the urban sector, considerable expansion of the wastewater-treatment plant has become necessary, affecting primarily the aeration basins and the secondary clarifiers. A future dry-weather inflow of ca. 144 000 m^3/d is anticipated, with an increase in the COD to

ca. 180 t/d, a total phosphorus increase of ca. 800 kg to 2200 kg/d, and a maximum total nitrogen load of 11 t/d. This demand is to be met by the installation of eight aeration basins for simultaneous nitrification and denitrification (240 000 m^3), equipped with diffusion aerators, together with nine secondary clarifiers (surface area 16 300 m^2, depth 4 m). In addition, the primary clarifiers currently in use will be partially rebuilt for conversion into a two-stage biological phosphorus removal plant. The existing sludge-incineration plant will also be replaced by a drying plant, and in the interest of odor control, individual segments of the plant will be covered and the exhaust air will be cleaned with compost filters.

Figure 64. Aerial view of the Miles Inc. anaerobic wastewater-treatment plant at Elkhart, Indiana

The Wastewater-Treatment System of the Miles Inc. (Bayer Corporation since April 1, 1995), Pharmaceuticals Division at Elkhart, Indiana, USA. The Miles Inc. pharmaceutical production operation pretreats all wastewater prior to discharging it into the City of Elkhart's municipal wastewater-treatment facility. The pretreatment system of choice in this case was a Bacardi Corporation "Anaerobic Filter Treatment System." This system removes biodegradable wastes while at the same time producing a methane-rich biogas that is captured and used as fuel for the Miles power plant.

Approximately 6625 m^3/d of chemical-processing wastewater is treated by the Elkhart facility's wastewater-treatment plant (Fig. 64). This plant was designed to remove two types of contaminants. The first is suspended solids, which can be eliminated by gravity settling. These solids include biomass from fermentation together with filter media, carbon, and solids from washings in the manufacturing area. The second type of contaminant removed is organic compounds, which would impart an oxygen demand on the receiving waters if left untreated. The organics are treated by the Bacardi process after solids have been removed by gravity settling in the primary clarifiers.

Primary (Organic-Rich) Waste System. Approximately 1540 m^3/d of organic-rich wastewater containing an average 27 200 kg of COD is processed through two anaerobic reactors (b) connected in series (see Fig. 65). The waste stream is equalized for flow and COD-concentration in two 3030 m^3 equalization tanks (a). Overflowing the first equalization tank into the second and operating the second tank at a 50 % level permits about three days worth of equalization to be achieved.

About 90 % of the water feed is directed to the first anaerobic reactor, while the remaining 10 % is passed into the second anaerobic reactor along with effluent from the lead reactor. The anaerobic reactors are 3030 m^3 tanks packed with a plastic, channeled medium to which the anaerobic microorganisms become attached. The combined recycle and feed is pumped to the top of the reactor and allowed to flow downward through the medium. The system removes about 90 % of the organic compounds present while producing approximately 14 200 m^3 of biogas per day, about 60 % of which is methane. The biogas is compressed to ca. 2.4 bar and pumped into a natural gas line used to fuel the boilers at the power plant. The biogas pipeline can be heated to prevent freezing of the condensables during cold weather. Should the gas recovery system happen to fail, a backup flare system burns the gas before releasing it to the atmosphere.

The design loading rate for the lead reactor was originally 8 kg of COD per cubic meter daily. This rate was later increased to 12 kg m^{-3} d^{-1} on the basis of operational experience. It was originally anticipated that the system would achieve a 60 % organic removal rate in each reactor, equivalent to an 80 % removal overall. Actual demonstrated efficiencies have been in the range 70 – 80 % in each reactor, for an overall removal efficiency of ca. 90 %.

Secondary Waste System. Approximately 6625 m^3/d (5110 m^3 of secondary waste com-

Figure 65. Schematic diagram of the Miles anaerobic wastewater-treatment plant
a) Equalization tanks; b) Anaerobic reactors; c) Chlorination tank; d) Neutralization tanks; e) Caustic tank; f) Clarifiers; g) Sludge-holding tanks; h) Mixing tanks; i) Belt filter presses; j) Sludge hoppers

bined with 1515 m^3 of anaerobic effluent), containing ca. 13 600 kg of suspended solids and 13 600 kg of COD, are treated in the secondary system. These waste streams are initially processed in two staged neutralization tanks (d), each with a capacity of 39 m^3. The pH is adjusted as necessary, although the incoming stream is usually neutral. Polymers are then added to enhance the solids-settling characteristics, after which the wastewater is clarified in two parallel 380-m^3 clarifiers (f). The clarified effluent passes into the interceptor system of the City of Elkhart for subsequent treatment at the municipal wastewater-treatment plant. Solids removed from the clarifier are pumped to two 227-m^3 sludge-holding tanks (g). The sludge is subsequently pumped to one of two belt filter presses (i) where, with the aid of a polymer flocculant, it is dewatered to produce a cake with a solids content of ca. 35 %. The latter is conveyed to hoppers (j) for transport to a local landfill.

In the course of the overall wastewater-pretreatment regimen, Miles' average discharge of COD and suspended solids is reduced from 41 000 and 14 500 kg/d, respectively, to 10 990 and 1370 kg/d. This pretreatment-system effluent meets all regulatory requirements of the City of Elkhart.

The entire process is monitored and controlled by a central control system. Four microprocessors receive the input and relay their output to various field instruments that in turn control flow rates, tank levels, etc. A series of active graphic display panels indicates current conditions at either of two operator stations in the control room. Any parameter falling outside the control limits is printed out in the control room or, if it is critical, announced over a loudspeaker by a computer-generated voice synthesizer.

Odor Control. The Miles chemical wastewaters contain high levels of sulfates, so extensive odor control is necessary to control emissions. Special equipment is used to add chlorine to the anaerobic effluent as a way of reducing microbial activity, which would otherwise result in the production of objectionable sulfur compounds. In addition, a 3400-m^3/min scrubber collects air from the covered clarifiers, sludge tanks, belt filter press area, and primary waste zone and

treats it chemically to remove odor-producing constituents.

2.2. Anaerobic Treatment

2.2.1. Introduction

In *aerobic fermentation* (e.g., yeast production, isolation of single-cell bacterial protein) the production of biomass is usually the most important single factor (→ Single Cell Proteins ; → Yeasts). Although a high degree of substrate conversion is the primary aim in aerobic wastewater treatment (i.e., the activated-sludge process), large amounts of biomass (clarification sludge) also form simultaneously because of the aerobic nature of the phenomenon. The fundamental advantage of an aerobic treatment is that oxidative degradation of the carbon substrates provides the energy required for propagation of the microorganisms that act as the biocatalyst. From the standpoint of achieving a high space – time yield the limiting factor is often the supply of oxygen, a gas that is only slightly water soluble.

In *anaerobic fermentation* it is the formation of product that usually occupies the spotlight (generation of methane, or of alcohols, ketones, and organic acids). The main advantage of biological fermentation as a method of synthesis is that inexpensive substrates are converted to valuable disproportionation products with the simultaneous formation of carbon dioxide. Here it is the energy that is usually limiting, resulting in relatively little growth of the catalytic microorganisms compared to the aerobic case. Since the microorganisms serve as both reaction product and catalyst, it is advantageous to maintain a high catalyst concentration under an anaerobic regime as well. The fact that energy is seldom a limiting factor in the case of the alternative aerobic fermentation must be paid for with a considerable energy expenditure in the course of providing the oxygen supply. The energy limitation associated with anaerobic fermentation is a function of the formation of energy-rich products.

In analyzing the microbial formation of methane, two important aspects stand out: the fact that the methane is derived from waste materials (clarification sludge and agricultural wastes), and its applicability in the treatment of industrial wastewater. Waste-material utilization in this sense amounts essentially to a form of biological stabilization (odor reduction, destruction of pathogenic microbes, dewaterability) in the interest of transforming the waste into a fertilizer. Biogas that arises as a byproduct is utilized in meeting the energy requirements of the associated bioreactors, where surplus gas is either flared off or burned as a source of heat for agricultural barns [202–205]. The anaerobic treatment of industrial wastewater has become increasingly important in recent years as a result of environmental-protection legislation, rising energy costs (which also have an impact on the cost of producing oxygen), and problems with the disposal of excess sludge formed in aerobic treatment processes. Efforts are now being made to remove organic contaminants insofar as possible without external sources of energy, taking advantage of the biogas produced, where the desired level of purification is ultimately achieved with the aid of a subsequent aerobic biological-clarification step.

2.2.2. Basic Principles

Developments in production technology have frequently resulted in the concentrated local accumulation of highly organic-laden wastewaters, a factor that must then be taken seriously into account with respect to disposal technology. With conventional aerobic wastewater treatment (the activated-sludge process), however, the greater the organic load, the more problematic the process becomes, because the required level of oxygen transfer rapidly approaches limits that are both technical and economic in nature. The key objective associated with the biogas process described here is thus the development of a mature alternative solution to the overall problem of wastewater, including water that is heavily contaminated with organic substances.

Efforts are currently being made to find a solution based not on increasingly elaborate aeration techniques, but rather on a concept already practiced in nature. *Biogas* forms wherever organic material decomposes microbially in the absence of air (i.e., anaerobically). This gas contains methane and carbon dioxide in a 1: 1 to 3: 1

ratio, together with hydrogen sulfide to an extent that depends on the sulfate content of the substrate, as well as traces of nitrogen and hydrogen. Whereas the activated-sludge process in principle represents a "cold (biological) combustion," the biogas process might be regarded as a "cold (biological) pyrolysis." Thus, anaerobic wastewater treatment represents an industrial application of a natural principle, one in which there is no trade-off between ecology (reduction of the pollutant load) and economics (energy-rich oxygen transfer is avoided, and a useful product is formed: biogas). Ecology and economics instead become mutually interdependent, and in an optimal way (effective contaminant reduction is accompanied by the production of large amounts of biogas).

The fundamental advantages of anaerobic wastewater treatment are:

1) Energy-intensive oxygen transfer is avoided.
2) The energy content of the resulting biogas can be put to further use.
3) Very little excess sludge is formed, while at the same time up to 95 % of the organic contami-nation is converted into a combustible gas (see Fig. 66), constituting a case of true disposal.
4) Heavy metals are not subjected to oxidative mobilization, but rather to reductive precipitation (as heavy-metal sulfides), facilitating their orderly disposal rather than wider dispersal.
5) Aerosol formation accompanying oxygen transfer is avoided, as is the stripping out of volatile components.
6) Space – time yields (bioreactor performances) reach a level fundamentally unattainable in the activated-sludge process because of the limitations imposed by oxygen transfer.

Given the same organic load, excess sludge formation is lower by a factor of 10 in an anaerobic process, because the exclusion of oxygen means that only ca. one-tenth as much metabolic energy is available to the microorganisms compared to an aerobic process. To be able to exist with a limitation of this kind, anaerobic microorganisms find themselves under tremendous selection pressure in favor of mutants with high metabolic activity (thereby compensating for a low energy yield by increased throughput). From the point of view of waste disposal, "high throughput" with little excess sludge formation is particularly interesting. Until now, anaerobic microorganisms have always been considered "sluggish" because of their low rate of multiplication, but this characterization ignores their high metabolic activity.

Figure 66. Carbon balances in the (A) anaerobic and (B) aerobic microbial degradation of organic compounds

Figure 67. Energy balances in the (A) aerobic and (B) anaerobic degradation of acetic acid

Figure 67 uses the biological transformation of acetic acid – a central intermediate in anaerobic degradation – as a vehicle for comparing anaerobic and aerobic processes. Taking into ac-

count external combustion of the biogas formed in the anaerobic case, the limitations associated with the two approaches become comparable. In anaerobic degradation the products consist of a small amount of biomass and a combustible, gaseous substance. The aerobic case leads to more biomass, and the simultaneous generation of heat. In principle, the newly formed biomass is also combustible, but only after a considerable expenditure of energy for separation and drying.

Acquiring a more than empirical understanding of anaerobic wastewater treatment forces one to examine more closely the interactions between the various microorganisms in a food chain. The basic scheme is depicted in Figure 68. In simplified terms, at least three groups of microorganisms are involved in the degradation of complex organic molecules. To begin with, biopolymers are first hydrolytically degraded in the context of acidogenesis to give soluble monomers. This is followed by acid formation, with the simultaneous generation of hydrogen and carbon dioxide, a step referred to as acetogenesis. It is at this point that methane formation can commence. Indeed, tracer experiments have shown that ca. 70 % of the methane produced in the overall process comes from the degradation of acetic acid [206], whereas the remainder arises from the reaction of hydrogen with carbon dioxide. The complete degradation chain is in reality much more complicated, and requires a balanced cooperation among the various microorganisms present, ensuring that there will be neither a shortage nor an accumulation of intermediates (see Section 2.2.3).

Figure 68. Schematic representation of the course of anaerobic methane generation from complex organic substances

Figure 69. Methane formation from acetic acid and the combination of hydrogen and carbon dioxide: the influence of hydrogen on propionic acid degradation

Another erroneous preconception – that anaerobic microorganisms are only able to degrade "chemical plain fare" – has been refuted by results demonstrating that the spectrum of degradable compounds is very wide indeed, encompassing even chlorinated aromatics [207–210]. This is not surprising when one considers that the decomposition of waste in nature occurs largely in the absence of oxygen. Thus, the observed low rate of natural degradation is a function of the low rate at which the relevant organisms multiply, although it was long misinterpreted as being due to poor degradability of the waste itself.

The central problem from a reaction-engineering point of view is finding a way to achieve space – time yields that are high, as in the anaerobic case. The more complex the substrate mixture from a chemical structure and particle size standpoint, the more difficult it becomes to meet this challenge. The growth of anaerobic microorganisms is a function of numerous factors, including residence time, temperature, redox potential, pH, and nutrient composition. From a thermodynamic perspective, hydrogen is a particularly important "intermediate." If hydrogen utilization is not sufficiently effective, then the equilibrium position of the preceding steps is influenced in an unfavorable way. The kinetics of the most important individual steps (Fig. 69) are so far quite inadequately understood. This is in part because of the complexity of the sub-

strate mixtures usually encountered in practice, but also because collecting reliable kinetic data is a very time consuming process, and possible only in the case of continuous fermentation.

Since the generation time for the microorganisms involved is comparatively long, the residence time of the catalyst must be uncoupled from the residence time of the substrate if one hopes to increase the space – time yield. To this end, various approaches are available for retention and recycling of the catalytic biomass. Furthermore, biological systems react sluggishly to changes in the supply of substrate, so it is necessary that there be developed an "intelligent" control technique taking into account the various factors mentioned. This is the reason why it is important to discuss here certain fundamental principles of reaction engineering relevant to the anaerobic mode of operation, with special emphasis on biomass retention and recycling as a way of achieving high space – time yields. From the standpoint of wastewater treatment it is also advisable that easily separable solid particles be removed from the influent stream in order to avoid an unwanted accumulation of solids in the course of subsequent efforts to retain or recycle the biomass.

2.2.3. Thermodynamics

As shown in Figure 68, the anaerobic degradation of organic 'matter proceeds via a series of intermediate steps. In terms of both thermodynamics and kinetics, further degradation may be severely limited if intermediates are allowed to accumulate. The concentration of hydrogen takes on a regulative role by influencing the distribution of metabolic products formed by the fermentative bacteria [211–214]. This point is emphasized in Figure 68 and reinforced by Equations 2.1 – 2.5 (Scheme 1) involving the products of acidogenesis (acetic acid, propionic acid, and butyric acid) and the hydrogen produced from them.

While the decomposition of acetic acid is independent of the partial pressure of hydrogen, the degradation of propionic acid and butyric acid would be inhibited by a high partial pressure of hydrogen. At the same time, an adequate hydrogen partial pressure is necessary for the formation of methane from hydrogen and CO_2 (either directly or via acetic acid). This results in a narrow "thermodynamic window" within which the decisive reactions are able to proceed simultaneously (see Fig. 70). It follows that there must be a close correlation between microorganisms that form hydrogen and those that instead utilize it (*interspecies hydrogen transfer*). Hydrogen transfer presupposes a spatial proximity on the part of the relevant microorganisms. In fact, if the population density is inadequate, vigorous stirring can actually interfere with this synergistic effect.

Figure 70. "Thermodynamic window" for simultaneous methane formation from propionic acid, butyric acid, and H_2/CO_2 as a function of hydrogen partial pressure ($T = 25°C$, pH = 7.0)

Figure 70 shows that propionic acid in particular is poorly degradable in the presence of even a low partial pressure of hydrogen. If hydrogen utilization in a mixed culture is not sufficiently high, accumulation is observed, especially of propionic acid (and the wastewater reactor "turns acidic"). Since the activity of methanogenic microorganisms decreases significantly at a pH below 5, a vicious circle is thus likely to result. Relevant data collected by LETTINGA et al. are presented in Figure 71 [115], which shows the acid concentrations at the out-

$$CH_3-COOH \rightleftharpoons CH_4 + CO_2 \quad (2.1)$$

$$CH_3-CH_2-COOH + 2H_2O \rightleftharpoons CH_3-COOH + CO_2 + 3H_2 \quad (2.2)$$

$$CH_3-CH_2-CH_2-COOH + 2H_2O \rightleftharpoons 2CH_3-COOH + CO_2 + 2H_2 \quad (2.3)$$

$$4H_2 + CO_2 \rightleftharpoons CH_4 + 2H_2O \quad (2.4)$$

$$4H_2 + 2CO_2 \rightleftharpoons CH_3-COOH + 2H_2O \quad (2.5)$$

Scheme 1. Products of acidogenesis

let of an anaerobic wastewater reactor in the first few days after startup. It will be noted that acetic acid and butyric acid become increasingly subject to degradation, whereas the concentration of propionic acid remains approximately constant. In such a case it is essential that the growth of hydrogen-utilizing microorganisms be encouraged by controlling the pH or prolonging the residence time to ensure adequate degradation of hydrogen and organic acids. The residence time can later be reduced again, using the partial pressure of hydrogen and the concentration of propionic acid as indicators of any threat of renewed overloading of the reactor (see Section 2.2.8).

Figure 71. Relative distribution of lower fatty acids after startup of an anaerobic fermenter (based on [115]) triangles = acetic acid; circles = propionic acid; diamonds = butyric acid

In practice, however, the relationships are much more complex, because it is not only propionic acid already present that may serve as an input to acetogenesis, but also additional propionic acid derived from prior steps in the context of acidogenesis. The equations below show that fermentative conversion of carbohydrates in the presence of hydrogen is directed mainly toward propionic acid, because this step is linked to the greatest change in free energy (ΔG_R^0: -358.1 kJ/mol).

$$C_6H_{12}O_6 + 4H_2O \rightarrow 2CH_3COO^- + 2HCO_3^- + 4H^+ + 4H_2$$
$$\Delta G_R^0: -206.3\,\text{kJ}$$

$$C_6H_{12}O_6 + 2H_2 \rightarrow 2CH_3CH_2COO^- + 2H_2O + 2H^+$$
$$\Delta G_R^0: -358.1\,\text{kJ}$$

$$C_6H_{12}O_6 + 2H_2O \rightarrow CH_3CH_2COO^- + 2HCO_3^- + 3H^+ + 2H_2$$
$$\Delta G_R^0: -254.6\,\text{kJ}$$

$$C_6H_{12}O_6 + 2H_2O \rightarrow 2C_2H_5OH + 2HCO_3^- + 2H^+$$
$$\Delta G_R^0: -225.9\,\text{kJ}$$

$$C_6H_{12}O_6 \rightarrow 2CH_3CHOHCOO^- + 2H^+$$
$$\Delta G_R^0: -198.3\,\text{kJ}$$

2.2.4. Kinetics

Anaerobic wastewater treatment can be accomplished under either *mesophilic* or *thermophilic* conditions. The advantages and disadvantages of the two alternatives are indicated in Table 9. With regard to activity of the microorganisms, thermophilic treatment offers no general

advantages. In fact, stability is greater in the mesophilic mode of operation. Although thermophilic fermentation does offer certain advantages from the standpoint of wastewater sanitization this is offset by an increased thermal requirement for preheating the substrate. However, thermophilic reaction conditions can be considered for wastewater that has a temperature at the bioreactor inlet of at least 60°C. Thermophilic conditions apparently result in the selection of a narrower spectrum of microorganisms, leading to more clearly defined but less stable conditions. Even though mesophilic conditions are accepted most widely today, the question of temperature selection still cannot be clearly answered, because results presented in the literature are frequently contradictory [216–224]. These discrepancies are caused not only by the various types of wastewater investigated, but also by a still inadequate understanding of thermophilic microorganisms.

Table 9. A comparison between mesophilic and thermophilic anaerobic fermentation

Characteristic	Mesophilic *	Thermophilic *
Activity	o	o
Stability	+	−
Sanitization/ "sterility" **	o	+
Thermal demand	+	−

* + = advantageous; − = unfavorable; o = average.
** Sanitization = elimination of pathogens; "sterility" = reduction of living-cell numbers.

In practice, only continuously operated systems can be used for kinetic measurements, because batch-reactor experiments (shaken cultures) provide results that are poorly reproducible. This is due to the fact that in a batch experiment the reaction conditions change constantly over the course of the test period resulting in the appearance and disappearance of various limitations. In a chemostatic operating mode the reactor is maintained at a steady state with respect to outlet conditions. The influence of various parameters can thus be studied by varying either the residence time or the substrate composition. The basic procedure for collecting kinetic data can be illustrated by using as an example the anaerobic degradation of acetic acid with a pure culture of *Methanosarcina barkeri*. This example is also of practical importance, because most biogas comes from the degradation of acetic acid, and this reaction is regarded as the limiting step. The extent of the kinetic data available for anaerobic treatment of wastewater itself with pure cultures is still much too small to be of use.

In studying the growth of *M. barkeri* (DSM 804), acetic acid was used as the sole source of carbon, with a defined mineral growth medium of the composition specified in the caption to Figure 72. An elemental analysis of *Methanosarcina barkeri* growing on this medium revealed carbon (46.85 %), nitrogen (12.16 %), hydrogen (6.69 %), sulfur (1.05 %) and phosphorus (0.91 %). Equation 2.1 for the methanation of acetic acid shows that a pH shift should be expected during the conversion process. Since optimal growth of this particular microorganism is possible only in a very narrow pH range (Fig. 73), it is necessary that the pH be held constant. Making a definitive statement regarding the course of the pH requires an examination of the dissociation equilibria for acetic acid and carbonic acid:

Figure 72. Schematic representation of the experimental setup for obtaining kinetic data regarding the anaerobic degradation of acetic acid by *M. barkeri*
a) Gas flow meter; b) Gas analyzer (CH_4, CO_2); c) Analysis of acetic acid and biomass
Growth medium (concentrations in parentheses in mmol/L): Acetic acid (1000), Na^+ (35); NH_4^+ (10), K^+ (5), Ca^{2+} (3), Mg^{2+} (2), S^{2-} (1.25), $HPO_4^{2-}/H_2PO_4^-$ (1), L-Cysteine (0.85), Fe^{2+} (0.55); Trace elements: Co, Ni, Mn, Se, Zn; Mo (<10 µmol/L); Vitamins: Wolfe's vitamins (≤1 µmol/L); pH_R (pH in the reactor) = 6.3; T = 37°C; V = 5 L [225]

Figure 73. Relationship between acetate degradation and pH in a culture of the mesophilic species *Methanosarcina barkeri*

$$CH_3COOH \rightleftharpoons CH_3COO^- + H^+$$

$$CO_2^g \rightleftharpoons CO_2^{aq} \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^- \rightleftharpoons 2\,H^+ + CO_3^{2-}$$

It is clear that the pH should increase with increasing degradation of acetic acid and decrease with the formation of CO_2. In addition, one must also take into account the solubility equilibrium of carbon dioxide. Figure 74 A shows the total concentration of carbonic acid (i.e., the sum of dissolved CO_2, hydrogencarbonate, and carbonate) as a function of pH. With increasing pH the concentration increases rapidly as a result of a shift in the dissociation equilibrium in favor of hydrogencarbonate and carbonate. The extent of CO_2 dissolved physically was calculated according to Henry's law for a partial pressure of 0.45 bar at 37°C, assuming that the saturation concentration is independent of pH.

$$[CO_2] = [CO_2\ \text{aq.}] + [HCO_3^-] + [CO_3^{2-}]$$

$$[CO_2\ \text{aq.}] = 11.4\ \text{mmol/L};\ T = 37°\text{C},\ P_{co^2} = 0.45\ \text{bar}$$

With the help of the dissociation constants for the various species involved, and taking into account the solubility of carbon dioxide, the expected course of the pH can be calculated. Figure 74 B shows a set of corresponding pH – conversion curves determined for various starting pH values for the conversion of a 0.3-mol/L acetic acid solution. If one assumes a conversion of 90 % and a pH optimum of 6.4, then in the case of an 0.3-mol/L solution the reaction should be initiated with a pH of 4.0 at the inflow in order to reach the pH optimum of 6.4 in a continuously operated stirred-tank reactor or in a reactor sys-tem with complete backmixing.

Figure 74. A) Overall concentration of carbonic acid as a function of pH ($T = 37°$C, $C_{CO_2\,(aq)} = 11.4$ mmol/L, $p_{CO^2} = 0.45$ bar) [226], [227]
B) A series of pH – conversion curves for acetate degradation ($S_0 = 0.3$ mol/L; $T = 37°$C; $p = 1$ bar; no buffer) [226], [227]

A schematic representation of the experimental arrangement used in this study is shown in Figure 72. The stirred-tank reactor was equipped with pH-measuring and control devices, a redox indicator, two coordinated pumps

for substrate dosing and product withdrawal, thermostatic control, a thermal mass-flow meter (a), and a gas analyzer (b) for methane and carbon dioxide. Substrate flow was determined with the aid of a balance.

To establish a set of model parameters it was necessary to solve simultaneously the substrate and the biomass balances for a stationary state in a continuous stirred-tank reaction without biomass retention:

Mass balance for the substrate (S = substrate concentration; X = cell dry-mass concentration):

$$0 = -\frac{1}{\tau}(S_0 - S) + \frac{\mu_{\max}}{Y_{\max}} \cdot \frac{S}{K_m + s} \cdot X + mX$$

Mass balance for the biomass:

$$0 = -\frac{1}{\tau} \cdot X + \mu_{\max} \cdot \frac{S}{K_m + s} \cdot X$$

Model parameters (acetate degradation by *M. barkeri*):

- $\mu_{\max}$ = maximum growth rate = 0.206 d^{-1}
- $Y_{\max}$ = maximum growth-yield coefficient = 1.533 g/mol
- K_m = Michaelis – Menten constant = 4.01 mmol/L
- m = maintenance factor = 2.88 mmol/L
- $t_{2/1}$ = generation time = 80.66 h
- τ_{crit} = critical residence time = 116.84 h
- $\tau_{\max}$ = residence time for maximum space-time yield = 124.24 h

Reaction conditions for continuous measurement:
S_0 = initial substrate concentration = 1000 mmol/L
pH = 6.3
T = 37°C

This leads to the following equations for the two variables X and S, obtained by solving for the biomass concentration X and the substrate concentration S:

$$X = f(\tau) = \frac{S_0 - S}{\tau \cdot \left(\frac{\mu_{\max}}{Y_{\max}} \cdot \frac{S}{K_m + S} + m\right)}$$

$$S = f(\tau) = \frac{K_m}{\mu_{\max} \cdot \tau^{-1}}$$

Figure 75. Maximum specific growth rate $\mu_{\max}$ established from a plot of the observed growth rate μ vs. the stationary substrate concentration S, where X = cell dry-mass concentration; $\mu_{\max} = 8.593 \times 10^{-3}$ h, $K_m = 4.01 \times 10^{-3}$ mol/L [228]
—— Calculated; ∗ Measured

Figure 76. Comparison between measured and observed volume-specific gas formation (space – time yield) and biogas yield in the degradation of acetic acid (S_0 = 1 mol/L, τ_{cr} = 117 h) [228]

Simple Michaelis – Menten kinetics were assumed for the growth of the microorganisms. The model parameters $\mu_{\max}$ (maximum growth rate), $Y_{\max}$ (maximum growth – yield coefficient), K_m (Michaelis – Menten constant), and m (maintenance factor) above were obtained by nonlinear regression from seven different experiments, each involving a different residence time, waiting always to make certain that stationary conditions had been established. The concentrations of acetate and biomass and the

formation of biogas were measured at equilibrium ($dS/dt = 0$, $dX/dt = 0$). Based on the measured quantities it was possible to achieve a 100 % closed-carbon balance. The generation time ($t_{2/1}$), the minimum residence time (τ_{cr}) leading to biocatalyst being washed out, and the residence time corresponding to a maximum space – time yield (τ_{max}) are derived quantities arising from this model.

The maximum specific growth rate μ_{max} and the Michaelis – Menten constant K_m can be determined by nonlinear regression by plotting the specific growth rate μ (in the form of the reciprocal of the residence time in the stationary state) against the stationary substrate concentration S (Fig. 75). With the help of the model parameters, the volume-specific biogas production rate and the biogas yield are also subject to calculation as a function of residence time. Calculated results are compared with the corresponding experimental data in Figure 76. It will be noted that the residence time for a maximum space –time yield is exceptionally predictable with an adequate degree of accuracy. It is also clear that even a slight variation in the residence time can lead to washing out of the microorganisms. Residence times that are only slightly larger than the critical residence time τ_{cr} results in a high biogas yield, because the K_m value for acetate (see above) is only 4 mmol/L, so a zero-order reaction is observed over most of the conversion range. The carbon balance associated with conditions of maximum space – time yield is further elaborated in Figure 77. In principle this represents an example of substrate carbon selectivity. Of the converted substrate carbon, only 3.12 % is incorporated into new biomass, while about 97 % is recovered in the biogas. Most of the latter is formed in the course of providing sufficient ATP for carbon incorporation (growth). Additional ATP is required to assure energy metabolism (maintenance). The resulting numbers clearly reveal the energy-limiting nature of the anaerobic fermentation process, but also the fact that true "disposal" occurs in the course of anaerobic wastewater treatment, since roughly 97 % of the carbon source is converted to biogas.

Figure 77. Selectivity in the utilization of substrate carbon, as illustrated by the example of aerobic methanization of acetic acid at maximum space – time yield [228]
$\tau = 124.24$ h; yield = 94.06 %; $x = 1.41$ g/L ● Biomass; △ Growth; ■ Maintenance

Figure 78. Optimization of selection stress by maximizing the space – time yield

A further increase in biomass activity could be achieved by successively reducing the residence time in the chemostats. This fundamental procedure also illustrates the basic idea behind the concept of selection-stress optimization by maximizing the space – time yield (Fig. 78), thus permitting an optimally adapted pure or mixed microbial population with maximum activity to be obtained in the shortest possible time [229]. The residence time should continue to be reduced so long as the space – time yield increases.

Figure 79. Increase in biomass activity [kilograms of COD per kilogram of cell dry mass (CDM) per day] of methane-producing bacteria through manual and computer-controlled reduction in the residence time

The residence time must be increased slightly if washing-out occurs – and not simply with respect to less active parts of the population, but for parts with higher activity as well. Continuous attempts should then in any case be made to increase the flow once again as soon as the population has recovered. Figure 78 illustrates the changes that may occur with increasing or decreasing residence time (horizontal arrows). A process computer outfitted with a control strategy for flow adjustment represents the best possibility for actually carrying out such an iterative approach to stress optimization (see Section 2.2.8). It has proven feasible in this way within six months to more than double the specific activity of a conventional enrichment culture relative to a 5-L or 10-L stirred-tank reactor. Over the course of another three months this value was improved further to 14.1 kg of COD per kilogram of cell dry mass (CDM, biomass) per day by manual adjustment (Fig. 79). Finally, after another three months the value had been increased to 20.1 kg COD/(kg CDM · d) with the aid of computerized set-point control. Compared with conventional experiments in a 5-L chemostats, the overall specific activity of the methanogenic population was ultimately quadrupled.

2.2.5. Mass and Heat Transfer

The anaerobic treatment of wastewater occurs essentially without any heat of reaction, which means that heat-exchanging surfaces are unnecessary. Nevertheless, since a bioreactor operates above ambient temperature, insulation of the outer walls is advisable. In fact, simply warming the substrate up to reaction temperature meets the primary heat requirement. To some extent it is possible to utilize the heat capacity of the effluent flow for heating purposes. Heat losses can be compensated without difficulty by combustion energy derived from the biogas produced. Thus, operation of an anaerobic wastewater-treatment plant is at least self-sustaining from an energy standpoint.

A biogas plant becomes all the more self-sufficient in energy the higher the organic-contaminant level of the wastewater and the higher its initial temperature. At a wastewater temperature of 10°C the concentration of organic components, expressed as COD (chemical oxygen demand), must be at least 7 kg/m^3. At a temperature of 30°C a COD level of 2 kg/m^3 is sufficient to cover the process-energy demands. Additional biogas produced at higher levels of organic contamination can, after desulfurization, be burned as necessary in a gas boiler for direct generation of steam.

Since no gaseous substrate (oxygen) is required, problems related to creating a large surface for material exchange are avoided. However, it is necessary that provision be made for the rapid removal of gaseous reaction products to ensure that as little of the "catalyst surface" as possible is blocked by gas bubbles. As a result of the residence times involved and the difference in density between the emerging biogas and the liquid phase (which provides a stirring effect), mechanical stirring aimed at mixing the liquid phase can be more or less dispensed with. When mechanical stirrers are used their primary purpose is to ensure homogeneous distribution of the catalyst or the suspension of solids. The energy requirement associated with fermenter circulation is 5 W/m^3.

Figure 80. Yield as a function of residence time in a backmixing reactor (tubular reactor with a relative return flow *R*) [227]
CSTR = Continuous stirred-tank reactor.

2.2.6. Reactor Design

Fermentation displays typical autocatalytic behavior (i.e., a portion of the product functions simultaneously as a catalyst), and since K_m values for the most important substrates are very small, every effort must be made at least with soluble substrates to approximate stirred-tank conditions. The literature includes both theoretical treatments and experimental examples suggesting the applicability of plug-flow conditions, but most of this information relates to secondary effects (biomass retention, partial utilization of solid substrates). Plug-flow behavior has also been recommended for the reduction of product inhibition [230], but there have to date been no convincing experimental applications.

The superiority of the stirred-tank reactor or a similar reactor system with complete backmixing has been clearly documented by simulated data based on the kinetic constants for *M. barkeri*, plotted in the form of conversion vs. residence time (Fig. 80). It is immediately obvious that the stirred-tank reactor offers the lowest reaction volume up to high levels of conversion. In the case of the backmixing reactor with low return flow ($R = 0.1$), the same conversion requires a residence time that is longer by a factor of 3. As the extent of back mixing increases, the conversion behavior approaches that of a continuous stirred-tank reactor (CSTR). Achieving approximately the same conversion, however, requires a return-flow ratio of 10: 1. It is nevertheless remarkable that even higher conversions can be attained with a still-finite return-flow ratio and a reasonable residence time (e.g., $R = 10$ with a 150-h residence time, as shown in Fig. 80).

Another approach to reducing the reaction volume entails the use of reactors connected in series, with a tubular reactor serving as the second stage. The stirred-tank reactor should then be operated in such a way that conversion in the first stage corresponds to the maximum value along the reaction-rate curve, equivalent to a minimum in the curve presented in Figure 81. However, given the pronounced substrate affinity of methanogenic microorganisms, the reaction is zero order over most of the conversion range relevant to actual practice (>90 %), so the effort required for the second reaction rules out any commercial interest. Strictly speaking, however, these observations apply only to a continuous stirred-tank reactor in which there is no biomass retention, because – as described later (see Section 2.2.7.6, "Influence of Residence – Time Distribution on the Microbial Degradation Kinetics") – the maximum space – time yield in a reactor system with biomass retention occurs at a significantly lower level of COD conversion (70 – 85 %), and use of a cascade leads to a marked reduction in the required reaction volume.

Figure 81. Inverse of the reaction rate plotted against COD conversion for a stirred-tank reactor [227]

As a result of stepwise degradation involving various bacterial populations, together with the complex interactions linking fermentative acid formation with methanogenesis, it has been suggested that these two individual steps be separated in space by the use of a multistage reactor combination [231–233]. The most widely applied variant is a two-stage mode of operation (Fig. 82), in which acidogenic microorganisms are most active in the first stage and mainly methanogenic microorganisms in the second [234–239]. The latter is usually implemented in the form of an upflow anaerobic sludge blanket (UASB; see Section 2.2.7.2) or fixed-bed reactor (Section 2.2.7.3). Single-stage operation typically entails a lower initial investment than a two-stage system, presumably the most important reason for the proliferation of single-stage commercial facilities in the 1970s and early 1980s. Today, however, the trend in anaerobic treatment of highly contaminated wastewater is clearly toward a two-stage process design. A comparison of these two variants based on the example of anaerobic treatment of wastewater from ethanol distillation (spent wash) is discussed in Section 2.2.7.6. The generation time of microorganisms in the first stage is clearly shorter than that in the second stage, so incorporation after the first stage of a sedimenter with partial biomass return is sufficient to maintain stable conditions in the first stage. Nevertheless, in a large-scale operation it is extremely important to ensure effective separation of preacidification biomass from the inlet of the second stage to prevent solids loading either in the methanogenic stage or at the outlet of the plant complex as a whole.

2.2.7. Biomass Retention/Recycling

Achieving high performance in a reactor is not simply a function of the biomass activity. Because of the autocatalytic factor the biomass concentration is important as well. The biomass concentration cannot be adjusted independently of the wastewater residence time in the bioreactor. Given the long generation time of anaerobic microorganisms, important components of the mixed population are always lost along with the partially treated water even at a residence time of several days if no precautions are taken with respect to biomass retention or external separation and return. In general, this requires increasing the particle size and/or the density difference relative to the liquid phase.

The most important methods for decoupling the residence times for liquid substrate and biomass in anaerobic wastewater treatment via

either internal retention or external separation and recycling can be summarized as follows:

A. Biomass retention (internal)
1. Sedimentation by pellet formation
1.1 Upflow Anaerobic Sludge Blanket (UASB) [239–244]
2. Filtration
2.1 Membrane Anaerobic Reaction System (MARS) [245]
2.2 Rotor-fermenter [237], [246]
3. Immobilization by adsorption or colonization of open-pored carrier materials
3.1 Fixed-bed reactor [247–256]
3.2 Fixed-bed loop reactor [257–268]
3.3 Anaerobic film reactor [269–278]
3.4 Fluidized-bed reactor [245], [279–293]
3.5 Hybrid concepts (UASB/fixed bed) [294–297]
3.6 Stirred-tank reactor with suspended carriers [298], [299]
4. Immobilization by inclusion or covalent bonding [300], [301]

B. Biomass recycling (external separation)
5. Sedimentation by chemical or physical separation
5.1 Anaerobic contact process (flocculation/lamella separator) [302–307]
5.2 Centrifugation
6. Flotation [308], [309]

Figure 84. Reactors for the immobilization of microorganisms in anaerobic wastewater treatment
A) Fixed-bed reactor; B) Fixed-bed loop reactor; C) Fixed-film reactor; D) Fluidized-bed reactor

Various approaches to biomass retention are illustrated in Figure 83.

A selection in favor of either flocculating or pellet-forming microorganisms that sediment easily in a bioreactor is still accomplished in most cases by empirical optimization of the reaction conditions. This principle of biomass retention is the basis for the upflow anaerobic sludge blanket (UASB) reactor [240–244]. It is difficult to reproduce pelletization, however, and there is also the risk that the biogranulates will subsequently redissolve. Free biomass or pelletized biomass can be separated with the help of filtration techniques, depending on the pore size of the filter [227], [245], [246], although such filters easily become clogged. Moreover, activity losses must be anticipated due to the mechanical shear stress involved in recirculating a microbial suspension. The practical applicability of this approach to wastewater reactors is thus severely restricted. At present, microfiltration is not utilized anywhere in large-scale anaerobic wastewater treatment.

One way to achieve an increase in the particle size, with a corresponding improvement in the separability of the liquid phase, is to immobilize the biomass on a carrier material. Evidence for the potential of this approach to microbial retention is available from nature, because most microorganisms in the environment are present in a fixed state. Nevertheless, adsorption presents the risk that the biomass might become detached as a consequence of shear forces. Efforts to counter this obstacle include binding biomass covalently to a carrier and enclosing it in a gel. The method has so far resulted in essentially no practical wastewater-treatment applications, however, because of frequent simultaneous inactivation of the biomass and the unacceptably high costs involved in covalent fixation. The colonization of macroporous carriers with high surface areas lowers the risk of biomass detachment and circumvents the cost entailed in covalent fixation, while at the same time substantially increasing the amount of biomass that can be accumulated per unit volume. Proper adjustment of the pore size of the carrier material permits the flow partially to penetrate the interior of the particles without also detaching the biomass. This has the further advantage that it facilitates the rapid removal of biogas as it is formed. A summary of common reactor configurations based on immobilized microorganisms is provided in Figure 84 [245], [247–293].

In the case of external biomass recycling, sedimentation is achieved either by flocculation induced by chemical additives, or by increasing the separation area with the help of lamella separators. This technique is also known as the *anaerobic contact process* [302–307]. It is also possible to increase the density difference by flotation, or to increase the gravitational field by centrifugation. The principles of exter-

nal biomass recycling are illustrated schematically in Figure 85. Practical bioreactor designs for the anaerobic treatment of wastewater are discussed in the sections that follow.

Figure 85. Schematic representation of methods for biomass recycling in the anaerobic contact process
A) Foam removal through flotation; B) Separation by external chemical or physical sedimentation

2.2.7.1. The Anaerobic Contact Process

This particular variant is based on external sludge separation and return to the methane reactor, and it attracted attention for practical wastewater treatment at an early date because of its limited technical requirements [302], [303]. The natural settleability of microorganisms is in this case increased either by the addition of organic flocculation aids or through the use of lamellar surfaces. Both approaches are employed in industrial applications. Continuous centrifugal separators might in principle be utilized as well, but this has not yet been implemented in practice. A microorganism concentration of 5 – 10 g/L (based on solids) is achievable through biomass recycling. Two major problems arise in the recycling of flocculent sludge, however:

1) Suspended sludge tends to form at sludge loads greater than 1 kg COD/(kg CDM · d).
2) Sedimentation in the settling tank is greatly impeded by secondary fermentation and gas formation. One remedy involves keeping the temperature low in the settling tank; alternatively, the sludge must be degassed under vacuum before entering the settling tank [310].

As a result of a low biomass concentration and low sludge load, the maximum achievable space – time yield is 3 – 5 kg COD m^{-3} d^{-1}. The superficial velocity in the sedimentation tank is ca. 0.5 m/h. Large plants based on this type of reactor have been built mainly for processing concentrated wastewater from the food industry (ANAMET process [306], [307]). About 80 large-scale contact-process plants are currently in operation worldwide. A major disadvantage is the considerable space requirement. Figure 86 is a photograph of a plant using the ANAMET process and built for use in the sugar industry. The lamella separators are clearly visible in the foreground.

Figure 86. Photograph of an anaerobic treatment plant based on the contact process and utilized in the sugar industry (COD load: 15 000 kg/d)

2.2.7.2. Upflow Anaerobic Sludge Blanket (UASB) Reactors

A simplified flow diagram of the UASB process is presented in Figure 87. Wastewater flows vertically through the system starting at the bottom. Microbial pellets sediment on the reactor floor, forming a sludge bed. Enrichment of the biomass in the reactor is made possible by a three-phase separation system designed especially to minimize any disruptive influence on the part of biogas during sludge separation. Apart from granulate sludge, a considerable amount of flocculated

sludge is formed as well, which in turn constitutes a basis for the formation of new pellets.

Figure 87. Schematic representation of the upflow anaerobic sludge blanket (UASB) process
a) Sludge – liquid inlet; b) Gas screens; c) Settled-sludge return opening

A distributor on the floor of the reactor is used for uniform liquid feeding, and it must necessarily meet special design requirements. This distributor consists of a system of polypropylene tubes laid in a defined way and fixed to a concrete plate. Each tube assumes a prescribed hydraulic load determined by the cross section of the tube and the number of outlets provided. Recirculation of partially purified wastewater to the UASB reactor is required only in the case of high COD concentrations in the wastewater in order to avoid pronounced concentration gradients as a function of height. Experience has shown that the height of the system should not exceed ca. 6 m, because uncontrollable hydraulic conditions would otherwise result owing to gas coalescence. This in turn generally also entails a considerable amount of surface area.

Wastewater fed into a UASB reactor should be acidified as completely as possible. The process chain is enhanced by a preceding preacidification step, which simultaneously ensures hydraulic equilibration. Granulate formation, of crucial importance for the proper functioning of a UASB plant, is influenced in part by the solids content of the reactor. A high proportion of inert solids may prevent pellet formation and thus the successful application of the concept.

Figure 88. A two-stage UASB treatment facility used in the starch industry (COD load: 28 800 kg/d)

Most of the large-scale wastewater-treatment plants designed for anaerobic operation – 129 as of January 1989 [311] – were conceived as UASB plants. This speaks well for the idea, but there are also disadvantages to be considered. For example, the process of microbial pellet formation is still very empirical, and it is neither applicable to all types of wastewater nor uniformly reproducible. The formation of granulated sludge may occasionally require several months or even years, and sometimes it never takes place; moreover, existing pellets may redissolve and be washed out of the system due to a change in process conditions. For this reason, pellet sludge is extracted from existing plants for the purpose of "seeding" newly commissioned UASB reactors, and material may even be transported overseas to this end. An examination of the utilization efficiency of the existing reactor volume shows that only 25 % of the space is actually devoted to bioconversion, while the rest functions simply as a phase-separating device. The biosolids concentration approaches 75 – 85 g/L in the granular sludge region, but the specific sludge activity with respect to acetate conversion (methanogenic activity) amounts to only 0.2 kg COD/(kg CDM · d) as a result of hindered mass transport. This in turn limits the

COD-elimination capacity (at maximum space–time yield) to ca. 6–14 kg COD m^{-3} d^{-1} [312].

The minimum realizable residence time in a UASB reactor is 2–6 h. However, such short residence times are actually achieved only with lightly contaminated wastewaters (1–2 kg COD/m^3). A residence time of 8–20 h is required for a moderately concentrated effluent (COD 3–20 kg/m^3). In the years 1976–1982 UASB reactors were installed primarily in the Netherlands for the treatment of wastewater from the sugar industry. However, starting about 1985 such plants also began to appear in conjunction with the starch, beverage, and paper industries. Figure 88 is a photograph of a two-stage UASB plant constructed for the starch industry.

2.2.7.3. Fixed-Bed Reactors (Anaerobic Filters)

Reactors with this configuration, in which microorganisms are fixed onto stationary carrier materials, were developed primarily in the United States as a response to problems encountered with sludge retention in the contact process [247]. As a result of pressure drop in the bed there is a lower limit of practicality for the size of the carrier particles utilized. In addition, a fixed bed easily becomes clogged from biomass growth or the accumulation of solids from the wastewater. It is advisable to use coarse, lumpy carrier materials made of stone, ceramic, or plastic with a diameter of 6–10 cm. The specific surface available for immobilization is thus restricted to 150–300 m^2 per cubic meter of reactor volume.

Other disadvantages are a consequence of the plug-flow nature of the process, which is undesirable from a reaction-engineering point of view (see Section 2.2.6). The associated pH and substrate-concentration profiles over the bed depth result in corresponding inhomogeneities with respect to the type, density, and activity of the microorganism population. Near the bottom of the fixed bed, fermentative (acidogenic) microorganisms predominate at a pH of 3.8–4.5 before acid degradation and increased pH in the upper regions combine to produce acceptable environmental conditions for methanogenic microorganisms. A low flow rate may encourage the accumulation of a high biomass concentration on the biofilms due to minimal shear stress, but the specific activity of the biocatalyst nevertheless remains extremely low on account of serious restrictions on mass transport. Increasing the length of the reactor causes a steadily increasing fraction of the cross section to be blocked by emerging biogas. For this reason, the capacity with respect to COD degradation for industrial-scale reactors of this type is restricted to 4–10 kg COD m^{-3} d^{-1}.

Figure 89. Anaerobic fixed-bed reactor of the Bacardi Corporation at Puerto Rico, designed for the treatment of residues left behind after alcohol distillation [248]

The residence time in an anaerobic filter is ca. 2–8 d. The first commercial plant of this type was built in the United States as early as 1973 for the anaerobic treatment of wastewater from the wheat-starch industry [313]. Other plants followed in the early 1980s in Europe, Canada, and South America for the purification of industrial wastewater and animal residues. A plant installed in Puerto Rico by the Bacardi Corporation for treating residues from alcohol distillation is especially impressive because of the size of the reactor [248]. With a tank volume of 12 500 m^3 this anaerobic-filter system is the largest single-stage biomethanation plant in the world. Figure 89 is a photograph of the Bacardi fixed-bed reactor. It is designed for downward flow, and is filled with 9900 m^3 of PVC honeycomb structures. A wastewater inflow of ca. 1400 m^3/d results in an average residence time of 9 d and an inflow COD load of 95 kg/m^3 at a load rate per unit volume of 10 kg COD m^{-3} d^{-1}. The ca. 25 000 m^3 of biogas produced each day is used for steam generation. Start-up of the reactor required ten months.

Figure 90. Two-stage anaerobic fluidized-bed reactor for treating wastewater from baker's yeast manufacture by Gist Brocades, Delft, Holland [314]

2.2.7.4. Fluidized-Bed Reactors

With this bioreactor concept, carrier particles covered with biomass are maintained in a fluid state by an upward flow of the wastewater. The disadvantages of anaerobic filters outlined above do not apply here because a superficial liquid velocity of 30 – 50 m/h provides almost complete back mixing and virtually unimpeded liberation of biogas. Further advantages of the fluidized-bed technique include:

1) The possibility of treating wastewater containing solids without the need for physical pretreatment
2) Simultaneous continuous discharge of excess sludge, which makes periodic sludge removal unnecessary
3) Increased specific biomass activity because of a reduction in mass transport resistance in the relatively thin biofilms owing to an increase in the convection current
4) Low space requirements associated with a compact design (height-to-depth ratio $\gg 1$ with a height of 15 – 20 m)

In general, natural minerals like quartz sand, meerschaum (sepiolite), and other silicates with particle sizes of 0.15 – 0.30 mm can be used as carrier materials. Since these present smooth surfaces, and the microorganisms are subject to immobilization only by adhesion (electrostatic and van der Waals forces, hydrophobic interactions), excessive shear stress causes considerable abrasion and the loss of biomass. This factor represents the most serious disadvantage of the fluidized-bed reactor configuration.

Pioneering work in the field of anaerobic fluidized-bed technology was conducted by the Dutch company Gist Brocades in Delft. It was found that the microbial tendency towards adhesion could be enhanced by maintaining the residence time in the reactor below the generation time of the bacteria, in this way providing selection pressure in favor of sessile mutants [300]. As early as the late 1970s pilot plants (V_R = 3.6 m^3) of this type began anaerobic treatment of wastewater from the baker's yeast industry. The first analogous large-scale plants were constructed in the early 1980s. Mixed wastewater

from the baker's yeast industry consists largely of condensate from the evaporation of a heavily contaminated split stream mixed with contaminated spray water and cleaning water. A typical COD load is 4.5 kg/m^3. Figure 90 is a photograph of such a two-stage plant, comprising two identical fluidized-bed reactors. Each of the reactors has a volume of 390 m^3 and is 21 m high. Quartz sand (140 t/reactor) serves as the carrier. The fluidized-bed volume is 215 m^3. An important design factor in the reactor head is a phase-separating device for the removal of biogas adhering to the biomass. The onset of methanation required four months. Peak values as high as 52 kg m^{-3} d^{-1} were subsequently achieved during a residence time of 3 h for COD elimination. It must also be noted, however, that it was the fluidized-bed volume – interesting from a chemical engineering viewpoint – that serve as the basis for calculating the performance data, not the total reactor volume, which is so crucial with respect to plant construction. Moreover, total volume is the decisive factor in process-engineering design for anaerobic wastewater treatment, so it would have been preferable if this had been taken as the basis for reporting performance data. In the preceding example, the space – time yield would then be reduced by almost 50 %, and the residence time would correspondingly be doubled.

Figure 91. Scanning electron micrograph of a Siran sphere (particle size ca. 2 mm; porosity 55 %; pore diameter 60 – 300 µm)

Problems subsequently arose in reproducing pilot-plant performance under full-load operation. Inadequate colonization of the carrier was found to be the cause, which resulted in a subsequent expansion of the facility. According to available verbal information, the plant is now being operated as a UASB system.

Another example of the practical application of anaerobic fluidized-bed techniques was announced in 1982 [293]. This report refers to the treatment of brewery water in ANAFLUX reactors based on the carrier Biolite, an aluminum magnesium silicate.

The use of porous carrier materials as an alternative to sand represents an especially interesting development in the fluidized-bed concept, although it has so far only been put into practice on a pilot scale. In conventional fluidized-bed reactors, loss of biomass is common due to abrasion related to inevitable shear forces, because only the outer surface of the carrier particles is available for the adsorption of biomass. Especially in conjunction with this reactor concept a macroporous carrier material like Siran, which microorganisms can colonize in a three-dimensional way, is far superior to materials subject only to external surface coverage [315], [316]. Figure 91 is a scanning electron micrograph of such a Siran pellet (for further details about pellet preparation and pore structure, see Section 2.2.7.5).

Figure 92. Schematic illustration of a fixed-bed loop reactor

Using as an example the anaerobic treatment of vapor condensates from the pulp industry,

an elimination rate of 250 kg COD $m^{-3}\,d^{-1}$ has been achieved with a loading rate per unit volume >300 kg COD $m^{-3}\,d^{-1}$. The corresponding biogas productivity was 160 $m^3\,m^{-3}\,d^{-1}$, from which the potential of this technique is abundantly clear. Nevertheless, practical applications in the wastewater sector are probably still rather remote because of the high cost of the carrier material.

2.2.7.5. Fixed-Bed Loop Reactors

The principle underlying this type of reactor combines the advantages of fixed-bed and fluidized-bed reactors, but avoids several of the disadvantages of both (Fig. 92). Most of the liquid responsible for the upward flow in a fixed-bed loop reactor [257–268] leaves the fixed bed and returns once again through an external loop, where it is mixed with fresh influent. Circulation is gradually increased until concentration gradients no longer play a role. Establishing the correct rate of circulation requires that biomass accumulation in the intergranular volume also be taken into account. This in turn means that the void volume must be neither rinsed entirely free of biomass nor allowed to become clogged. In this way it is possible to establish a very high biomass concentration. Thus, despite the low propagation rate of anaerobic microorganisms, provision must be made for periodically washing out excess sludge by briefly increasing the circulation rate. Simultaneously, small suspended solid particles not trapped in the course of physical pretreatment of the wastewater, and which may have accumulated in the fixed-bed loop over time, are also flushed out.

This particular anaerobic-reactor concept has become especially familiar in the literature in conjunction with the use of macroporous carrier materials for microbial immobilization with three-dimensional colonization. The technique itself leads to an increase in particle size and an increase in the density difference between the particles and the fluid, making it possible to decouple the residence time for the biocatalyst and the fluid in the reactor without the addition of chemicals (e.g., for carrier fixation, flocculation, or flotation) or supplementary energy (e.g., for filtration or centrifugation), and also without the need for constructing additional facilities (e.g., sedimenters or lamellar separators).

Figure 93. Scanning electron micrographs at various magnifications showing an open-pored sintered glass that has been formed into Raschig rings

On account of their low density, organic polymers frequently used for carrier purposes, such as polyurethane foams [267], [317], are not advantageous in this case, because such a carrier would float on the surface and require confinement with nets. The circulating stream would then need to be directed downward, impeding

the release of biogas. For this reason inorganic materials are much more effective, including lava slag, a naturally occurring macroporous carrier. An alternative is Siran, a commercial sintered-glass material with adjustable properties, manufactured by Schott Glaswerke, Mainz. A homogeneous mixture of the starting materials, glass, and salt powder of a defined particle size is first sintered, and the cooled material is subsequently extracted with water, resulting in structures with porosities as high as 70 %, together with a defined pore-size distribution. The production process lends itself to carriers of almost any shape (e.g., Raschig rings, pellets). Figure 93 is a scanning electron micrograph of a Raschig ring made of sintered glass depicted at various enlargements.

Basic process-development work in this area was initiated in the 1980s at the Forschungszentrum Jülich (Jülich Research Center, Germany), leading eventually to establishment of the "biogas high performance process" for treating heavily organic-laden wastewaters. This process was successfully commercialized over a period of several years by licensing it to various parties interested in building treatment plants.

The first large-scale plant of this type was for a potato-starch factory, and it took only ten months to build, with operation commencing in September, 1987. Figure 94 provides both a flow diagram and a photographic overview of the two-stage facility. It incorporates a preacidification tank with a working volume of 1000 m^3. Four fixed-bed loop reactors (d; 300 m^3 each) for methanization are connected in parallel. These are filled with lava slag that serves as the porous carrier. The plant is designed for a hydraulic load of 2000 m^3/d, resulting in a residence time of 14 h for the methanization reactor (second stage) at a loading rate per unit volume of 30 kg COD $m^{-3}\,d^{-1}$. Operation under full hydraulic load leads to the anaerobic elimination of more than 20 t of COD per day. At a COD/BOD ratio of 1.7, this corresponds to about 200 000 population equivalents. The process in turn generates ca. 12 000 m^3 of biogas per day. The exceptional efficiency of microbial colonization in conjunction with a macroporous carrier is apparent from the fact that this plant was able to operate at full capacity within six weeks. Seven large-scale plants of this type are currently active. Apart from the one described above, similar plants have been built for the pulp and paper industry, baker's yeast fermentation, and feed manufacture. In the latter application peak values $\leq$106 kg COD $m^{-3}\,d^{-1}$ have been achieved without difficulty in facilities with capacities of 20 and 170 m^3 through the use of Siran Raschig rings with projected space – time yield of 35 kg COD $m^{-3}\,d^{-1}$.

2.2.7.6. Engineering Considerations

Scale Transfer and Dimensioning of Anaerobic Fixed-Bed Loop and Fluidized-Bed Reactors. Little information is available in the literature regarding scale transfer and dimensioning for anaerobic reactors with integrated provision for biomass retention (e.g., UASB reactors, fixed-bed and fluidized-bed reactors). Apart from systems based on the fluidized-bed technique, all the plants are relatively flat, with a *H/D* ratio $\leq$1. As a result of a variety of limi-

tations (e.g., low biomass concentration and activity in the contact sludge process, considerable loss of biomass with increasing gas velocity in UASB plants, and the formation of concentration and pH gradients in consequence of the plug-flow behavior of filter reactors) the space – time yields with respect to COD degradation do not exceed 15 kg COD m^{-3} d^{-1} from a design standpoint.

Industrial high-load plants [space – time yield ≤ 80 kg COD m^{-3} d^{-1}] operating under conditions comparable to those associated with the large-scale projects already realized (e.g., the biogas high-performance process) remain a rarity. According to [311], it is possible to achieve loading rates per unit volume >60 kg COD m^{-3} d^{-1} under optimized conditions in a UASB plant. The corresponding operating conditions would however require simultaneous development of new sludge-separation devices for installation at the reactor head to ensure the efficient retention of biomass pellets. Such a facility might be described as a "floating – settling granular-sludge UASB plant."

The trend toward further establishment of high-load treatment plants – more than 130 industrial facilities are currently operating throughout the world – is clear from efforts now underway to perfect this especially promising approach to anaerobic wastewater treatment. Nonetheless, the scale-up of anaerobic wastewater treatment has never been studied in a systematic way and for a variety of reasons (e.g., the absence of free exchange of experience, inadequate basic knowledge on account of a "black box" attitude). Of all the methods devised for model transfer in chemical process engineering, especially the similarity principle and modelling theory, the latter is most applicable to the conditions associated with anaerobic wastewater treatment, and it has also been accepted as the most useful starting point.

From a chemical reaction-engineering viewpoint, anaerobic fixed-bed loop reactors and fluidized-bed reactors behave almost like well-mixed, continuously operated stirred-tank reactors under discharge conditions (i.e., under circumstances where there is no appreciable pH or substrate-concentration gradient). The result is a source term for emerging product that remains constant over the entire height of the reactor. But since the product is a gas mixture (CH_4/CO_2) that is only slightly soluble in water, there is a height-dependent linear gas accumulation that increases as the height of the reactor increases. In the course of scaling up to the next larger version of a bioreactor (increased height or increased biogas production) it is necessary to anticipate extensive biogas flooding in the upper bed regions to an extent dependent on the *H/D* ratio. This means that the effective hydraulic residence time in the reactor will decrease in an indefinite way, leading to a corresponding reduction in conversion, and inevitably also to a decrease in the space – time yield in the larger unit relative to a laboratory-scale plant.

The following central question thus arises in the practical scaling up of the reactor types discussed here: In a large scale plant, what is the maximum practical bed height, or how small might the volume-based reactor cross-section be so that biogas release will not have a limiting effect on the overall bioprocess?

It is possible to approach a solution by introducing a process-dependent influencing parameter that takes adequate account of the issues raised above. The "surface gas-loading rate" (or "gas loading per unit area", GLA) with dimensions m^3 m^{-2} h^{-1} can be regarded as such a quantity. This characterizes the number of cubic meters of newly-formed biogas released from the anaerobic reactor per cubic meter of reactor cross-sectional area per hour. The surface gas-loading rate increases in a linear way with increasing column height, and reaches a maximum that limits the further release of biogas, thus inevitably establishing a maximum permissible bed height. This maximum height is a function of the nature of the process in the case of the fixed-bed or fluidized-bed technique, and of the particle size if a resting carrier is used. The requisite design-dependent volume can then be achieved simply by adopting the corresponding cross section.

Appropriate experiments with fixed-bed loop reactors (containing 7- and 25-mm Siran Raschig rings and 32 – 50-mm lumps of broken lava slag) as well as fluidized-bed reactors (Siran pellets with a diameter of 1 – 2 mm) have provided the desired maximum values for surface-gas loading rate from the observed gas hold-up. The reactor heights together with the carrier-bed heights were increased stepwise until sharp decreases in performance became apparent. The

following surface-gas loading rates were established in this way:

7 mm Raschig ring/fixed-bed loop reactor:	3.19 $m^3\,m^{-2}\,h^{-1}$
25 mm Raschig ring/fixed-bed loop reactor:	6.9 $m^3\,m^{-2}\,h^{-1}$
32 – 50 mm lava slag/fixed-bed loop reactor:	8.5 $m^3\,m^{-2}\,h^{-1}$
1 – 2 mm pellets/fluidized-bed reactor:	19 $m^3\,m^{-2}\,h^{-1}$

The relationship between the maximum permissible bed height and volume-specific biogas production (space – time yield) is illustrated in Figure 95. It is clearly apparent that when the volume-specific biogas production assumes a value equal to the maximum gas-loading rate per unit area (GLA), the permissible bed height shrinks to only 1 m. Disregarding the 7-mm carrier particles (which are not suitable for practicalapplication in a fixed bed because the realizable bed height is too low and the potential for clogging is too great), use of carrier particles >25 mm in diameter definitely opens the way to plant heights of 8 – 14 m operating in a practical range of volume-specific biogas production.

Figure 95. Scaling (A) a fixed-bed loop reactor or (B) a fluidized-bed reactor: the relationship between maximum permissible height and volume-specific biogas production (VSBP)

Comparison of Single-Stage and Two-Stage Process Operation. Taking the anaerobic treatment of distillery residue as an example of dealing with a complex, highly organic-laden effluent from the food industry, it proved possible to define realistic limits for single-stage processing [318], [319]. A fixed-bed loop reactor like that shown in Figure 93 was used in this particular study. Very large fluctuations were observed in the fatty-acid spectrum in the reactor effluent, as well as in the hydrogen content of the biogas, despite the unchanging nature of the wastewater and an approximately constant residence time (Fig. 96). The observed propionic acid peaks clearly correlate with the hydrogen concentration, which serves to verify the relationship suggested by Figures 70 and 71. It should also be noted that an acetic acid peak accompanies each propionic acid peak (suggesting the conversion of propionic acid to acetic acid!).

Figure 96. Fluctuations in (A) fatty acid and (B) hydrogen concentrations in a single-stage fixed-bed loop reactor with a feed consisting of distillery residues
—- Acetic acid; · · · · · · Propionic acid; -·-·- Isobutyric acid; - - - - - Butyric acid; ——— Valeric acid

In view of these unsatisfactory results, a reactor configuration corresponding to that shown in Figure 83 was installed, along with a fixed-bed loop reactor for methanation. This particular reactor concept facilitated independent adjustment of the pH in the course of preacidification. A close relationship was discovered between the product spectrum in the effluent and the preacidification step as a function of pH. The formation of propionic acid can pose problems in the subsequent methanation stage, and the propionic acid level proved lowest when a pH of 4 was established in the preacidification stage. At this pH the organisms of the methanation stage are no longer active, however, which explains the absolute necessity for a two-stage procedure. Results for both single-stage and two-stage processes in the anaerobic treatment of distillery residues are presented in Figure 97. For every spaceload tested the attainable COD conversion was found to be greater in the case of the two-stage process, and process stability was greatly improved as well.

Figure 97. The effect of COD loading on COD conversion in single-stage and two-stage configurations for the degradation of distillery residues (COD loading = 34.5 kg m^{-3} d^{-1}; single stage configuration: 75 % conversion with $\tau = 25$ h, 89 % with $\tau = 35$ h; two stage configuration: 93 % with $\tau = 17$ h)

Influence of Residence-Time Distribution on the Microbial Degradation Kinetics. Since fermentation displays typical autocatalytic behavior, with part of the product simultaneously serving as a catalyst, and because K_m values (Michaelis – Menten constants) for the most important substrates are very small, efforts have been made to approximate stirred-tank behavior by virtually complete backmixing. The need for this remedy applies only so long as the stationary substrate concentration in the reactor is significantly higher than the semisaturation concentration, however. Should a higher level of degradation be desired, or if the K_m values increase (by an apparent decrease in substrate affinity) as a consequence of integrated measures taken to decouple the mass-transport dependent relationship between substrate residence time and biomass, a transition would be observed from a zero-order reaction to a first-order reaction. Under these conditions, use of a reactor system with limited backmixing (e.g., a cascade) would be feasible.

Wastewaters from the production of sauerkraut and from ethanol distillation were used to compare the two design variants in both single-stage and cascade methanation. Fixed-bed loop reactors were employed in all cases. A preceding stirred tank was used for preacidification of the wastewater. The investigation covered residence times of 5 – 16 h. COD effluent values from the cascade arrangement were in all cases clearly lower than those from effluent data for single-stage methanation. In fact, the observed differences were more pronounced (by up to 4 kg of COD per cubic meter) in the case of the more contaminated distillery residues compared with the moderately contaminated wastewater from sauerkraut fermentation. The clear superiority of the process involving a two-stage methanation cascade relative to a fixed-bed loop reactor is especially apparent from curves of the residual COD content as a function of residence time (Fig. 98). For a COD reduction of 80 % ($COD_e/COD_o = 0.2$), a residence time of ca. 13 h is required in the case of single-stage methanation. The residual content in effluent from a two-stage cascade with the same residence time is only 0.1, corresponding to a conversion of 90 %. A residence time of as little as 8 h is sufficient to degrade 80 % of the COD in the case of the two-stage process. Under these conditions, the observed volume reduction in a methanation cascade compared with the single-stage mode of operation is ca. 40 %.

Figure 98. Change in residual COD as a function of residence time in the anaerobic treatment of distillery residues via a two-stage process (a) with and (b) without a cascade arrangement
COD_e = effluent COD; COD_o = initial COD.

Results from all the reaction-engineering investigations so far reported for process design optimization with fixed-bed loop reactors in the anaerobic treatment of highly organic-laden effluents from the food industry are summarized in Figure 99, which shows the course of the minimum residence time and the associated relative methanation volume for a COD reduction of ca. 85 % at various developmental stages in the corresponding "process evolution." Accordingly, the volume of a two-stage cascade is only 3.5 % of that required for a continuously operated stirred-tank reactor (CSTR) lacking provisions for residence-time decoupling.

2.2.8. Control

The control concepts that are potentially applicable to anaerobic degradation can be illustrated with the case of acetic acid. To prevent acidification of the reactor due to insufficient substrate degradation, the substrate pump can be controlled via a pH electrode in such a way that substrate feed is interrupted as soon as the pH falls below a certain value. With this pH-auxostatic mode of operation (Fig. 100), wastewater feed is governed by a pH controller. The cleavage of acetic acid to CH_4 and CO_2 corresponds formally to a titration with an alkaline solution (see Fig. 74), so as the pH in the reactor rises this effect must be compensated by the addition of acidic substrate. Use of a proportional controller means that there will always be a difference between the actual pH and the desired value, and

the amount of substrate added is proportional to the magnitude of this difference. Since substrate introduction is in effect controlled by the degradation efficiency of the microorganisms, the microorganisms themselves determine how much wastewater will be fed to the reactor. 101

Alternatively, an alkaline pH might also be assured in the reactor by establishing a suitable pH for the influent. The target pH in the reactor must be sufficiently alkaline so that, in the case of a change in residence time or concentration, a slight decrease in the pH can be associated with an increase in the activity of the microorganisms. This chemostatic concept results in automatic stabilization so long as the operation is conducted on the alkaline side of the pH optimum with respect to the microorganisms. It is advantageous to safeguard the process by ensuring additional pH control on the acidic side of the pH optimum to prevent excessive drift into the acidic range.

The first approach has the advantage that the bioreactor always operates at maximum load, but it requires a buffer volume at the inlet to permit the controller to interrupt the substrate feed. On the other hand, the second approach excludes the possibility of continuous operation corresponding to maximum space – time yield. Nevertheless, it does avoid the need for a buffer volume, and there is no risk of uncontrolled preacidification.

Because of the low propagation rate of anaerobic microorganisms, considerable importance is attached to an optimal time-course for start-up of the biogas reactor, as well as to preventing damage to a cultivated biomass. Both objectives are most easily achieved with the help of modern computer-coupled control technology (Fig. 92). Thus, the set-points for the feedback control systems associated with the relevant parameters (residence time, temperature) are established in advance with the help of a personal computer based on the criterion of a maximum increase in the space – time yield. The amount of biogas generated, the pH, and the derivatives of these quantities as a function of time serve as indication values with this form of control. A definite level of degradation for the wastewater contaminants can be established as a secondary condition. Actual degradation can be determined online on the basis of the residence time and the extent of biogas production. A decision matrix is constructed from a combination of directly measurable and derived quantities, on the basis of which the computer adjusts the externally predetermined set-points consistent with observed trends.

The process configuration illustrated in Figure 102 made it possible to demonstrate in the anaerobic treatment of exhaust-steam condensates from the pulp industry, for example, that a greater than 3-fold increase in performance could be achieved within less than four weeks starting with a space – time yield of ca. 40 kg COD $m^{-3}\,d^{-1}$.

2.2.9. Future Prospects

The anaerobic treatment of wastewater represents another example of the fact that innovations may result from the joint application of

biological and industrial principles. Despite sophisticated optimization of the oxygen transfer process, aerobic wastewater treatment becomes less competitive with the anaerobic technique the higher the contamination level of the wastewater. The principle of carrier fixation as a way of preventing the washing-out phenomenon is also derived from a model frequently observed with sessile microorganisms in nature. On the other hand, minimizing limitations associated with diffusion problems by increasing the convection current is a typical industrial approach to problem-solving. Since energy required for this purpose can, in principle, be provided directly by gas-driven motors, the approach in question is justifiable even over the long term. In the case of highly contaminated wastewater, anaerobic treatment is not only energy self-sufficient, but also capable of providing excess energy for use in other applications. In addition, the resulting marked reduction in excess sludge production should constitute a weighty argument in favor of the anaerobic process.

Concerns related to heavy metal deposition in a wastewater reactor operating under anaerobic conditions have not yet been accorded sufficient attention despite the fact that the distribution of clarification sludge (e.g., from the activated-sludge process) on agricultural land has been curtailed because of excessive heavy-metal contamination. Wastewater treatment is an industrial process associated with one of the largest levels of mass throughput known, and for this reason it has provided a major impetus to further developments in bioprocess technology in general.

3. Aerobic Processing Steps in Process Combinations

This chapter represents a collection of the various processing steps in which the liquid – gas interface plays an important part in the purification of water or air.

Flotation is a technique for separating undissolved constituents from water, whereby the particles attach themselves to gas bubbles. Particles rising with the gas bubbles are removed at the surface as foam. As a rule, flotation processes compete with sedimentation processes for accomplishing a particular separation. Flotation can offer significant advantages over sedimentation, especially for poorly sedimenting and poorly thickening water constituents.

One application of flotation is in drinking-water treatment [320], especially for the clarification of surface waters contaminated with such poorly sedimenting particles as algae. Flotation is often used in this context as a preliminary purification step prior to filtration [321]. Later in the course of drinking-water treatment, flotation can be used for treating waterworks sludges or sludge-containing waters that arise from rapid filtration, sand washing, microstraining, coagulation and precipitating plants, or decarbonation [322].

In the purification of commercial or industrial wastewaters, including the recovery of valuable materials, flotation is useful especially for the separation of fibrous, flocculent, greasy, or oily materials [323]. Flotation is normally used in this context only to carry out decentralized partial cleansing upstream from a central biological wastewater-treatment unit [324], [325].

Flotation also forms a part of the overall process of biological wastewater treatment for separating and concentrating sludge [326].

Biofilters and *bioscrubbers* are devices used for the biological cleaning of waste air. Such biological waste-air cleaning processes compete most notably with adsorption, absorption, and thermal and catalytic processes. Biological waste-air treatment entails transferring some of the constituents of the air in question to an aqueous solution that is then oxidized by microorganisms, analogous to biological wastewater treatment. Another portion is consumed in the formation of cell mass [327–330].

In biological waste-air treatment a distinction is made between processes involving fixed microorganisms (biofilters and *trickle-bed bioreactors*) and those based on suspended microorganisms (bioscrubbers). In the case of fixed microorganisms, the waste-air flows through some type of microorganism-support layer, which in the case of a biofilter may consist of twigs or compost, whereas with a trickle-bed bioreactor system it would be a porous packing. In a bioscrubber the air contaminants are absorbed into water or an aqueous suspension of microorganisms in an absorption column. The absorbed contaminants are then degraded inside the regenerator, a bioreactor like that used in biolog-

ical wastewater treatment. The bacteria used in biological waste-air purification may originate from a wastewater treatment plant or from the soil. Their composition must first be adapted – as a rule over the course of several weeks – to the waste air subject to treatment. However, a regenerator unit might also be integrated through a recycle system with a biological wastewater-treatment facility, such as one designed for treating industrial effluents. If the air contaminants to be degraded happen also to be present in the wastewater, then microorganisms from the wastewater-treatment facility will already be sufficiently adapted to perform this supplementary function [331].

Biological waste-air purification was originally called upon most often for odor-reduction assignments, in conjunction for example, with intensive management of livestock or other agricultural problem areas. Wastewater-treatment plants also represent one of the traditional fields of application [332]. Biofilters find use in the influent treatment zones of wastewater-treatment plants, in the biological stages of both trickling filters and activated-sludge tanks, in sludge-treatment facilities, and in conjunction with such other equipment as flotation tanks or buffer tanks.

Biological waste-air purification has been increasingly applied to problems of other organic emissions in various industrial and commercial fields.

3.1. Flotation (see also Section 5.2.2.3; → Flotation)

3.1.1. Basic Principle

The principle underlying flotation is that gas bubbles rising through water are capable of transporting to the surface particles that may adhere to them, where these particles can then be separated with the foam. Flotation has been used in mineral technology for about a hundred years as a technique for sorting, i.e., for the separation of particles of different materials. A prerequisite for such sorting – for separating a valuable ore fraction from its matrix, for example – is that only one of the two components has a hydrophobic surface, thus permitting it to adhere to the gas bubbles, while the surface of the other component is hydrophilic and well wetted by the water. Since the hydrophilic particles adhere only weakly or not at all to the bubbles, they will not be transported to the surface, but instead remain in suspension or sink to the bottom.

In mineral technology, specially selected combinations of flotation aids are introduced for each specific separation. For example, materials known as *collectors* assume the task of conferring a hydrophobic character on the hydrophilic surface of certain components. These collectors are surface-active substances whose polar regions adhere to the solid surface, leaving the nonpolar parts oriented toward the surrounding water. *Foaming agents* have the function of preventing the rising particle-laden bubbles from bursting at the surface, instead causing the particles to bind in a foam that is sufficiently stable for separation. Foaming agents are also surface-active substances, but ones whose polar group is surrounded by water, permitting a nonpolar group to project into the air bubble. Finally, *modifying reagents* are added to influence the flotation process by way of the pH, or to intensify hydrophobicity differences between the components to be separated by passivation or activation of the collecting effect.

Various methods have been used to generate the corresponding gas bubbles. In convective bubble generation (*aeration* or *induced air flotation*) the gas stream (usually air that has been sucked or pumped into the system) is caused to disperse. Devices for this purpose include rotor–stator systems and nozzles, occasionally also porous aeration surfaces. In *pressurized dissolved-air flotation* the water is first saturated with gas at an elevated pressure and then depressurized to a lower pressure prevailing in the flotation apparatus. According to Henry's law, the solubility of a gas in a liquid is proportional to the pressure, so bubbles are produced in the course of this depressurization. Another important bubble-generation variant is *electroinduced air flotation*, in which gas bubbles are generated electrolytically. Some types of flotation apparatus take advantage of a combination of various principles. An important advantage of dissolved-air flotation is that the gas bubbles form preferentially at the surfaces of hydrophobic particles. For these particles, a transport step conveying them to the gas bubble is avoided, and

this is often the rate-determining phenomenon in aeration flotation.

Aeration flotation is most widely applied in mineral technology, in which it has long been regarded as a standard method for various sorting functions. In the past, mechanical flotation devices based on rotor – stator systems played a greater role than hydraulic or pneumatic flotation systems, into which energy must be introduced with a liquid pump or a gas compressor. *Countercurrent flotation columns* have become increasingly important since the early 1980s. In this case air is fed into the column from below, while wash water is charged from above. The suspension to be separated is introduced into the column about two-thirds of the way up from the bottom. This countercurrent principle confers greater selectivity on the separation process.

Bubbles generated by the dispersion technique in mineral technology aeration flotation are about 1 mm in diameter. Materials that are to be sorted by flotation are as a rule ground to particle sizes ranging from a few tens to a few hundreds of micrometers. Particles that are too coarse are no longer capable of being transported by the gas bubbles. In the fine-particle range, selectivity decreases; in particular, the fraction $<5\,\mu m$ enters a foam unselectively, since very fine particles will adhere to gas bubbles even if they have a low degree of hydrophobicity. Smaller bubbles in the approximate size range $50-100\,\mu m$ are formed in dissolved-air flotation, and in electroflotation a typical bubble size is only ca. $20\,\mu m$.

Flotation has become an accepted method for water-purification purposes since about the 1960s. The problem here differs from that in mineral technology in two important respects: first, flotation is used not for sorting but for clarification. Thus all the particles present must be transported to the surface by gas bubbles for separation with the foam. Second, the particle size involved is below the range of typical applications in mineral technology.

In water treatment, flotation represent an alternative to sedimentation. For mineral particles larger than about $40\,\mu m$, which have a settling rate >5 m/h and can thus be separated rapidly in settling tanks, no alternative method is necessary or suitable. For the fines fraction below about $5\,\mu m$, on the other hand, with settling rates <0.1 m/h, separation is no longer practical in a settling tank without flocculation. Flocs, even when composed of mineral particles, often have such a high fraction of pore volume that their settling rate is unsatisfactory irrespective of dimensions. Moreover, many of the particles to be separated in water treatment differ in density only slightly from the surrounding liquid. Examples include such organic contaminants as oil droplets or microorganisms, and especially activated sludge, which must be concentrated in the course of biological wastewater treatment.

Flocculants used in the flotation process for water treatment have another important function aside from producing flocs with a size and structure favorable to flotation: they serve to render the particles hydrophobic, and therefore to guarantee adhesion of the flocs onto the gas bubbles. The individual steps involved in particle flocculation and adhesion of the particles to gas bubbles often proceed simultaneously. The result is the formation of voluminous flocs in which gas bubbles have also been incorporated.

The same basic flotation principles developed for mineral technology are also used for water treatment. Mechanical flotation devices have never found application here, however – only hydraulic or pneumatic flotation systems, since bubble sizes $\leq 100\,\mu m$ have proven advantageous. Electroflotation has been applied successfully to certain types of problems, but by far the most important flotation method for water-treatment purposes is dissolved-air flotation.

Figure 103. Mechanisms for establishing contact between particles and gas bubbles
a) Diffusion; b) Sedimentation; c) Interception

3.1.2. Contact and Adhesion of Particles to Gas Bubbles;Flotation Kinetics

In both aeration flotation and electroflotation, contaminant particles must be transported to the gas bubble before the two surfaces can make contact with each other. The flow pattern around a rising gas bubble is sketched in Figure 103. Three important mechanisms can lead to contact between particles and bubbles suspended in a liquid.

First, a particle may make contact with a gas bubble through interception without its center ever leaving the streamline, provided the particle's radius is at least as large as the shortest distance from the streamline to the bubble. Since transport of the particles out of their streamline is not required, this contact mechanism cannot be classified as a transport mechanism.

Alternatively, particles might be transported by either sedimentation or diffusion (Brownian motion) away from a streamline and toward a gas bubble. (For particles in the size range of interest for water treatment by flotation – well under 100 µm – transport by inertial effects plays essentially no part relative to interception or sedimentation.)

For interception Figure 103 shows an example of the limiting streamlines for contact of a particle of diameter d_p with the bubble. These streamlines constitute a rotationally symmetrical tube around the vertical axis. All particles whose centers move toward the bubble within this limiting-streamline tube will inevitably make contact with it. On the other hand, particles with centers of gravity outside this limiting-streamline tube flow past the bubble without touching it. The cross-sectional area of the limiting-streamline tube at a great distance from the bubble is described as the *collisional cross-sectional area* A_ki for the contact mechanism of interception (i). The ratio of this collisional cross-sectional area to the projected area P_b of the bubble is described as the *single-bubble collision efficiency* η_i:

$$\eta_\mathrm{i} = \frac{A_\mathrm{ki}}{P_\mathrm{b}} = \left(\frac{d_\mathrm{ki}}{d_\mathrm{b}}\right)^2 \tag{3.1}$$

where d_ki is the collisional cross-sectional diameter for interception and d_b the bubble diameter. Another collisional cross-sectional area, A_ks, can be defined correspondingly for the sedimentation contact mechanism, in which particles are actively transported toward the bubble from the streamline. A collisional cross-sectional area A_kd must also be formally defined for the diffusion contact mechanism, although the transport mechanism in this case is not determinate, but stochastic. Single-bubble collisional efficiencies for sedimentation (s) and diffusion (d), respectively, can be expressed as:

$$\eta_\mathrm{s} = \frac{A_\mathrm{ks}}{P_\mathrm{b}} = \left(\frac{d_\mathrm{ks}}{d_\mathrm{b}}\right)^2 \tag{3.2}$$

$$\eta_\mathrm{d} = \frac{A_\mathrm{kd}}{P_\mathrm{b}} = \left(\frac{d_\mathrm{kd}}{d_\mathrm{b}}\right)^2 \tag{3.3}$$

The overall single-bubble collisional efficiency η_k is interpreted as the sum of contributions from interception, sedimentation, and diffusion:

$$\eta_\mathrm{k} = \eta_\mathrm{i} + \eta_\mathrm{s} + \eta_\mathrm{d} \tag{3.4}$$

Relationships describing these individual contributions are known from the theory of deep-bed filtration:

$$\eta_\mathrm{i} \sim \left(\frac{d_\mathrm{p}}{d_\mathrm{b}}\right)^2 \tag{3.5}$$

$$\eta_\mathrm{s} \sim \frac{g\,(\varrho_\mathrm{p} - \varrho_\mathrm{l})\,d_\mathrm{p}^2}{\mu \cdot u} \tag{3.6}$$

$$\eta_\mathrm{d} \sim \left(\frac{kT}{d_\mathrm{p}\,d_\mathrm{b}\,u}\right)^{2/3} \tag{3.7}$$

where g is the acceleration due to gravity, ϱ_p is the particle density, ϱ_l is the liquid density, μ is the dynamic viscosity, k is the Boltzmann constant, and T is the absolute temperature. Here u represents the incident velocity of flow on a spherical collector of diameter d_b. If u is defined as the bubble-rising velocity for bubble sizes $d_\mathrm{b} \leq 100\,\mu\mathrm{m}$,

$$u \sim \frac{g \cdot \varrho_\mathrm{l} \cdot d_\mathrm{b}^2}{\mu} \tag{3.8}$$

then the following modified relationships are obtained for η_s and η_d [333]:

$$\eta_\mathrm{s} \sim \frac{\varrho_\mathrm{p} - \varrho_1}{\varrho_\mathrm{l}} \left(\frac{d_\mathrm{p}}{d_\mathrm{b}}\right)^2 \tag{3.9}$$

$$\eta_\mathrm{d} \sim \left(\frac{kT}{g\,\varrho_\mathrm{l}\,d_\mathrm{p}}\right)^{2/3} \cdot \frac{1}{d_\mathrm{b}^2} \tag{3.10}$$

For relatively large particles whose densities differ very little from that of the liquid, interception is decisive, but with large density differences sedimentation predominates. For relatively small particles, diffusion represents the dominant contact mechanism.

Figure 104 shows the single-bubble capture efficiency in the case of a negligible density difference as a function of particle size, with the bubble size as a parameter [333], [334]. Taking into account both diffusion, dominant in the fines range, and interception, which dominates in the coarse range, it develops that there is a minimum capture efficiency for particle sizes around 1 µm. In order to avoid unsatisfactory flotation with particles in this size range, fine primary particles should be flocculated insofar as possible. In practice, therefore, interception and sedimentation are most often the contact mechanisms of interest.

Figure 104. Single-bubble capture efficiency as a function of particle size [333]

For all three contact mechanisms, the single-bubble collision efficiency decreases in inverse proportion to the square of the bubble diameter. For all particle sizes, therefore

$$\eta_k \sim \frac{1}{d_b^2} \tag{3.11}$$

Apart from the temperature and various material parameters, the proportionality constant contains only the particle size d_p. In other words, the collisional cross-section A_k is independent of the bubble size.

A second prerequisite for successful separation is adhesion of the particles to the gas bubble subsequent to collision. Decisive with respect to such adhesion is on the one hand van der Waals forces acting between the particles and the liquid, and on the other electrostatic interactions between the particles and the gas bubbles. These quantities are difficult to access by direct measurement. A reasonable starting point for evaluating the effectiveness of adhesion is the contact angle Θ between the liquid – gas interface and the solid surface at the three-phase contact line. Figure 105 illustrates the contact angle Θ for a drop on a planar solid surface as well as for a spherical solid particle at a planar gas – liquid interface. The contact angle Θ is established such that the total interfacial free energy of the solid – liquid (sl), solid – gas (sg), and liquid – gas (lg) interfaces assumes a minimum value. Young's equation

$$\gamma_{lg} \cos\Theta = \gamma_{sg} - \gamma_{sl} \tag{3.12}$$

describes the relationship between the corresponding interfacial free energies per unit area γ, also known as the *interfacial tensions*, and the contact angle Θ.

Figure 105. Contact angles Θ for (A) a spherical solid particle at a gas – liquid interface, and (B) a drop resting on a solid surface

As Figure 105 A illustrates, a particle penetrates more deeply into a gas bubble the larger the contact angle. Hydrophilic particle surfaces form a small contact angle with water, hydrophobic particles a large one. The strength of the bond between particle and gas bubble is greater the more hydrophobic the particle and the greater the contact angle.

The *adhesion probability* in the event of a collision between a particle and a bubble is designated here as η_h. This approaches zero as the contact angle Θ approaches zero. With increasing contact angle Θ the adhesion probability η_h approaches the value one. A quantitative description is difficult, since it requires comparing adhesive forces with disruptive hydrodynamic forces. The shear stress such a particle – gas bubble agglomerate experiences in the flow field increases more rapidly with the particle size than does the strength of the binding. For this reason small particles, which are the target of separation in water treatment, will adhere sufficiently well to gas bubbles even if they are only slightly hydrophobic and develop only a small contact angle with the liquid.

The single-bubble capture efficiency η is the product of the adhesion probability η_h and the single-bubble collision efficiency η_k:

$$\eta = \eta_h \cdot \eta_k \tag{3.13}$$

If the single-bubble capture efficiency η is known, the kinetics of particle capture by gas bubbles can be calculated. Over the time interval dt, gas bubbles with a rising velocity u pass through a layer whose thickness can be represented as

$$\mathrm{d}h = u \cdot \mathrm{d}t \tag{3.14}$$

within the flotation tank. The relative concentration reduction for freely suspended particles in the course of this ascent is

$$\frac{\mathrm{d}C}{C} = -\eta \cdot P_v \cdot C_{vg} \cdot u \cdot \mathrm{d}t \tag{3.15}$$

where

$$P_v = \frac{3}{2} \cdot \frac{1}{d_b} \tag{3.16}$$

P_v is the projected area per unit volume of the gas bubbles, and C_{vg} is the volume concentration of gas bubbles in the flotation tank. This is obtained as a ratio of the superficial gas velocity u_g and the rising velocity u of the gas bubbles:

$$C_{vg} = \frac{u_g}{u} = \frac{q_g/A}{u} \tag{3.17}$$

The superficial gas velocity can be described as ratio of the volumetric flow rate of the gas q_g and the cross-sectional area A. From integration of the equation

$$\frac{\mathrm{d}C}{C} = -\frac{3}{2}\frac{u_g \cdot \eta}{d_b} \cdot \mathrm{d}t \tag{3.18}$$

it follows that

$$\ln(C/C_0) = -\frac{3}{2}\frac{u_g \cdot \eta}{d_b} \cdot t \tag{3.19}$$

If a constant adhesion probability η_h is assumed, it follows from Equations 3.11 and 3.13 that

$$\eta \sim \frac{1}{d_b^2} \tag{3.20}$$

and

$$\ln(C/C_0) \sim -\frac{u_g}{d_b^3} \cdot t \sim -\frac{q_g}{d_b^3} \cdot t \tag{3.21}$$

The flotation-velocity constant

$$k = \frac{\ln(C/C_0)}{t} \tag{3.22}$$

is thus proportional to the gas throughput, and inversely proportional to the third power of the bubble diameter (i.e., inversely proportional to the bubble volume).

From this point of view, the bubble size should therefore be kept as small as possible. On the other hand, the minimum size of the bubble is limited by the requirement of adequate buoyancy and sufficiently high rising velocity even in the presence of attached particles. The bubble volume must as a rule be at least one order of magnitude greater than the volume of the largest particles to be separated. In practice, bubble sizes in the range of ca. 10 – 100 µm have proven advantageous for water-treatment flotation [335–338].

If, during aeration flotation, the bubbles are broken up by turbulent-flow processes, the ultimate bubble size is determined by the power per unit volume $\varepsilon = P/V$:

$$d_b \sim \varepsilon^{-2/5} \tag{3.23}$$

It follows that

$$\ln(C/C_0) \sim q_g \cdot \varepsilon^{6/5} \cdot \mathrm{t} \tag{3.24}$$

The flotation-velocity constant k thus increases in proportion to the gas throughput, and slightly more than proportionally relative to the power per unit volume.

3.1.3. Implementation, Fields of Application, and Operational Experience

The mechanical flotation devices widely used in mineral technology, in which power for dispersing the gas bubbles is introduced by rotor–stator systems, play virtually no role in water treatment.

Figure 106 shows an example of a hydraulic flotation device developed for wastewater treatment in the chemical industry [339] as well as for the separation and thickening of sludge in biological wastewater treatment [326]. Small bubbles about 150 µm in diameter are formed by a flared nozzle. Flotation tests with systems of varying material composition, in which the two process parameters gas throughput and liquid throughput were decoupled from each other by throttling the gas throughput, agreed in yielding the common relationship

$$k \sim q_g \cdot q_l^2 \tag{3.25}$$

Since the power per unit volume ε introduced by the jet of liquid is proportional to the square of the volumetric flow rate of the liquid q_l^2 it follows that

$$k \sim q_g \cdot \varepsilon \tag{3.26}$$

This experimental result approximately confirms the relationship found in the model calculation (Equation 3.24).

Figure 106. Aeration flotation [326]
A) A flotation cell with automatic flotate discharge; B) Detailed view of the flared nozzle (self-priming, with radial bubble generation)

Numerous examples of the application of a flotation cell with a flared nozzle like that illustrated (Fig. 106) can be found for wastewater treatment in the chemical industry, including the separation of an azo pigment or a crop-protection agent from wash water, separation of toluene from a toluene – water emulsion, and the removal of printer's ink from paper waste [339]. In the separation and thickening of sludge from biological wastewater treatment, biomass with an initial dry-matter concentration of 2 – 10 g/L was removed almost entirely from treated wastewater on a pilot-plant scale, resulting in a flotate with 20 – 30 g of dry matter per liter [326].

Aeration flotation is regarded as unsuitable for the treatment of drinking water [336]. In the wastewater field as well the advantages associated with dissolved-air flotation (see below) predominate more often than not [325].

A special form of dissolved-air flotation is dissolved-air flotation for the separation of sludge from wastewater treated in an aeration chamber exceeding 10 m in height (e.g., a Bayer tower-biology unit). Figure 107 shows a flotation cell developed for this particular purpose [326]. The aeration chamber is arranged concentrically within a cylindrical tank. Effluent from the tower biology flows through the flared nozzle in the aeration chamber, and the bubbles required for flotation form spontaneously as the external pressure is released from gas originally dissolved under the static pressure of the tower. Dissolved-air flotation therefore entails no additional energy costs. The flotate so obtained contains dry matter ranging from 20 g/L (brewery wastewater) to 80 g/L (wastewater from chemical plants) at permissible area-loading rates up to 8 m/h [$(m^3/h)/m^2$] [326], [340].

Figure 107. Flotation cell developed for dissolved-air flotation in conjunction with a tower-biology system [326]
a) Tower biology; b) Flotation cell

Under certain conditions, gas arising in the course of microorganism metabolism also can be utilized directly for flotation. For example,

gas generated during the anaerobic degradation of nitrate has been used for intermittent flotation of activated sludge with a flotation time between 4 and 48 h [341]. As a rule, however, dissolvedair flotation is applied in conjunction with a split stream of previously treated water that has been saturated with a gas in the pressure range 0.4 – 0.8 MPa, and subsequently led back via pressure-releasing elements into the flotation tank, as shown in Figure 108 [342].

Figure 108. Schematic representation of a typical dissolved-air flotation system

Figure 109. Air-bubble diameter distribution in dissolved-air flotation as a function of saturation pressure
a) 0.8 MPa; b) 0.6 MPa; c) 0.4 MPa; d) 0.2 MPa

Figure 109 illustrates the bubble-diameter distribution for air in water as a function of saturation pressure [342]. In the preclarification of chemical wastewater from the manufacture of organic intermediates, a relatively uniform solids-removal efficiency of 90 – 98 % was achieved by this technique at an area-loading rate ≤4 m/h by the addition of 20 % pressurized water at a saturation pressure of 0.4 MPa. Figure 110 shows the superiority of the process over sedimentation in a thickener [343]. This superior contaminant-removal efficiency in the preclarification stage of wastewater treatment leads to a noteworthy reduction in the burden placed on the subsequent biological treatment.

Figure 110. Comparison of the separation efficiency of dissolved-air flotation versus sedimentation [343]

Figure 111. Schematic representation of an electroflotation system [348]
a) Influent structure; b) Electrodes; c) Partition; d) Effluent structure

Dissolved-air flotation has proven particularly worthwhile in the context of grease- or oil-containing wastewaters from a wide variety of industrial and commercial sources, including the foods sector [344–347]. Dissolved-air flotation has also had wide success in drinking-water treatment where prior flocculation of the raw water is necessary [336].

Electroinduced air flotation is reserved for smaller mass fluxes associated with special types of problems, such as wastewaters derived from electroplating (see Fig. 111) [348] or oil – water

emulsions [349]. Electroflotation is uneconomical for large-scale applications [348] because of the high cost of the energy required for generating the gas bubbles.

3.1.4. Costs and Benefits

As an example of the operating costs (without capital debt service) of a flotation plant in wastewater treatment, the various process steps of neutralization, precipitation of organics with polymeric precipitants, flocculation, dissolved-air flotation, dewatering of the flotate with a filter press, and incineration of the dewatered sludge have been examined for a medium-sized decentralized wastewater stream of 50 m^3/h [325]. In an unfavorable case the overall operating costs may be as high as € 5 per cubic meter of wastewater. The largest shares are associated with the costs of chemicals and incineration: ca. € 1.5 per cubic meter each. Annual operating costs for 50 m^3/h of wastewater may amount to € 2.3×10^6.

The cost of flotation, which is the most universal approach to solid – liquid separation in decentralized wastewater treatment, is lower than that of evaporation or incineration by a factor of about 10. But the benefits of evaporation and incineration are also greater, since they result in complete disposal of highly contaminated effluent, whereas the precipitation and flotation processes discussed in the above example represent only a partial treatment of a moderately contaminated split stream. Since the value of this partial treatment is also a subject of some dispute it must remain an open question whether it is wise to spend € 2.3×10^6 annually for the pretreatment of a stream that comprises only a small fraction of the total wastewater from a large chemical plant [325].

Compared with sedimentation, flotation offers considerable advantages in many cases, not only in water treatment and recovery of valuable materials but also in the separation and thickening of sludge. As a rule, it leads to a higher dry-matter content for the resulting concentrate. Because of higher area-loading rates and shorter residence times, smaller apparatus volumes are required as well. This in turn generally implies lower investment costs, albeit at the expense of higher operating costs. A process comparison for drinking-water treatment of water for the River Ruhr yielded for sedimentation a space requirement 50 times greater than that for flotation. On the other hand energy costs for flocculation – flotation were found to be about 50 times greater than for flocculation – sedimentation [321].

Better opportunities exist with flotation than with sedimentation for control and adaptation to fluctuating operating conditions, although taking advantage of these opportunities requires the availability of more highly trained personnel.

3.2. Biofilters and Bioscrubbers

3.2.1. Basic Principle

Biological waste-gas purification, just like biological wastewater treatment, takes advantage of the metabolic capacity of microorganisms as a way of degrading and oxidizing organic compounds: to carbon dioxide and water, for example. Microorganisms are fundamentally able only to utilize materials dissolved in water. In aerobic biological wastewater treatment one of the most important technical challenges is dissolving sufficient amounts of oxygen in the water to permit propagation and metabolism on the part of the bacteria. With biological waste-gas purification there is the further problem that the compounds to be degraded must somehow be transferred into aqueous solution.

In a *biofilter* or a *trickle-bed bioreactor*, absorption and biological degradation of waste-gas components occur in a single step. With a *bioscrubber* the waste-gas components are first dissolved in water in an absorption column and then largely degraded in a regenerator coupled downstream. The operating principles of the biofilter, trickle-bed bioreactor, and bioscrubber are illustrated schematically in Figure 112 [350]. The biofilter and trickle-bed bioreactor both operate with fixed microorganisms. The organisms are fixed in the case of the biofilter on layers of such materials as twigs, heather, peat, compost, or other natural organic matrices, whereas the trickle-bed bioreactor utilizes an inert porous packing. Column fittings constructed from plastic, for example, are used in bioscrubbers. An aerated stirred tank or a hydraulic or pneumatic bioreactor can serve as the regenerator.

Figure 112. Basic operating principles associated with various biological waste-gas purification alternatives [350]
A) Biofilter; B) Trickle-bed bioreactor; C) Bioscrubber
a) Filter layer; b) Biocatalyst; c) Column; d) Regenerator

Biodegradation generally occurs with the aid of a mixture of various species of bacteria, actinomycetes, and fungi. In a biofilter the biomaterial serves not only as a support for the biofilm, but also as a source of moisture, and in some cases also of nutrient. Fungi and actinomycetes often predominate. In a bioscrubber, bacteria usually predominate. All nutrient is provided via the wash liquid containing the dissolved off-gas compounds that are to be degraded [351].

3.2.2. Prerequisites for Biological Waste-Gas Purification

Prerequisites for the growth and metabolic activity of microorganisms are a sufficient supply of nutrients and water as well as a suitable range of temperature and pH. Biological waste-gas purification with a bioscrubber requires supplemental addition of nutrients depending on the waste-gas composition, since biological regeneration of the scrubbing liquid would otherwise be impossible. In a biofilter, on the other hand, sufficient amounts of nutrients are available in the filter material. A precondition for adequate purification capacity with a biofilter is a sufficient and uniform supply of moisture. In practice, the moisture content is in the range 40 – 65 % depending on the filter material. The temperature range for most bioscrubbers and biofilters is 20 –40°C. The optimal and tolerable pH ranges vary considerably depending on the organisms involved. Most heterotrophic bacteria prefer neutrality, but mold fungi and yeasts are partial to slightly acidic conditions [351], [352].

3.2.3. Implementation, Fields of Application, and Operational Experience

Biofilters. The most widely used biofilters are single-level filters. Figure 113 illustrates the basic principle [329], [350]. If space is at a premium, several filter beds can be arranged above each other in tiers. The waste gas subject to treatment enters the filter bed from below through an air distribution system (e.g., perforated or slotted elements made of special concrete, plastic, or wood; gratings or ventilating bricks). The filter-bed height is typically 0.5 – 1.5 m. Filter area-loading rates fall in the approximate range of 20 – 300 $m^3/(m^{-2} \cdot h^{-1})$. Such single-level filters are constructed with surface areas up to ca. 2000 m^2 for the treatment of waste-gas streams as large as 100 000 m^3/h. Pressure loss in the biofilter itself is in the range 200 – 2000 Pa per meter of filter height [353]. Particularly in the case of relatively highly contaminated waste-gas, the biofilter is sized according to the specific filter loading, calculated from the extent of waste-gas constituents that will flow through the filter per unit of filter volume and time. The corresponding data (for organic carbon, for example) are reported in $g\,m^{-3}\,h^{-1}$. If the filter is to be used for odor removal, the loading can also be reported in odor units per cubic meter per hour.

Figure 113. Overview of a single-level filter utilized for biological waste-gas purification
a) Concrete base; b) Filter layer

The first biofilters were used as early as the 1920s for reducing odor emissions from waste-treatment plants. The odor problem in waste-treatment business has in the meantime assumed

an important role in licensing laws and ordinances. In the past it was necessary with many waste-treatment plants to add special facilities for the collection and treatment of waste air. Today, construction and operating licenses are granted for new plants near residential areas only if proposals for the reduction of possible odor emissions are submitted in the early planning stages [332]. Apart from scrubbers, whose mode of operation is exclusively chemical, biofilter units are the most important devices for waste-air treatment in the wastewater-treatment sector. Biofilters are utilized in conjunction with almost every waste-gas source: from the influent zone through the biological stage, sludge treatment, and even such areas as flotation facilities. Recommended standards include a maximum specific filter-loading rate of 2×10^6 odor units per cubic meter per hour, a reaction time of 50 – 90 s, and a filter area-loading rate of ca. $100\,m^3/(m^{-2}\cdot h^{-1})$ [332].

The use of porous support materials makes it possible to achieve higher cell densities, and therefore in some cases higher reaction rates, with a trickle-bed bioreactor than with a biofilter. A schematic overview of a trickle-bed bioreactor is presented in Figure 114 [350]. Reaction products harmful to the microorganisms (such as hydrochloric acid, formed during the conversion of chlorinated hydrocarbons) can be removed from the reactor.

Figure 114. Schematic representation of a trickle-bed bioreactor [350]

The greater resistance of fixed microorganisms to the influence of poisons, acids, or temperature fluctuations is regarded as an advantage common to both biofilters and trickle-bed bioreactors [350].

Bioscrubbers. A bioscrubber consists of two separate pieces of equipment. Gas constituents that are to be degraded are first absorbed in a scrubbing column, after which these substances are biologically degraded in aqueous solution in a regenerator. The size of the scrubbing column and the quantity of scrubbing liquid must be such that the requisite level of clean-gas concentration is reached even at maximum concentration and quantity of crude gas and maximum stationary residual concentration of organic substances in the solvent. The spray density must be set sufficiently high to avoid buildup of a biological film and consequent clogging of the packing. Based on experience, a spray density $>20\,m^3/(m^{-2}\cdot h^{-1})$ is required. Moreover, the regenerator must be so designed that organic contaminants are almost totally degraded. At the same time, the requisite oxygen content of at least 1.55 mg/L for biological degradation must be maintained in the activated-sludge tank by suitable aeration units [354].

Figure 115. A bioscrubber facility integrated into a wastewater-treatment plant for the purpose of odor reduction [331]
a) Scrubbing columns (H = 9 m; D = 3,2 m; three sieve trays each); b) Regeneration tank ($V = 30\,m^3$); c) Biological stage of a wastewater-treatment plant; d) Biosuspension recycle system ($200\,m^3/h$); e) Exchange recycle system for the regeneration tank ($60\,m^3/h$); f) Exchange recycle system involving the wastewater-treatment plant (ca. $5\,m^3/h$)

Compared with biofilters, bioscrubbers are distinguished by lower space requirements, higher space – time yields, and greater flexibility and adaptability. On the other hand, maintenance and operating costs are usually higher with bioscrubbers, as is energy consumption. Waste-gas constituents that are only slowly biodegradable demand a long biosuspension residence time, and thus a correspondingly large regenerator. Providing such conditions makes it advanta-

geous to integrate into the system the biological stage of an existing wastewater-treatment plant, which can serve as a superior reservoir for fresh biosuspension. Even with high contaminant concentrations and slowly degradable constituents it is then possible to get along with a relatively small regenerator. Figure 115 is a schematic illustration of such an integrated plant designed for odor reduction of a waste-gas stream of 60 000 m^3/h [331].

Figure 116. Bioscrubber in which the bioreactors are incorporated into the column plates
A) General operating principle [355]; B) Three-stage implementation [356]
a) Tray; b) Gas channel; c) Baffles; d) Slits; e) Bioscrubber trays with short absorption zones and long degradation zones

A new bioscrubber concept (Fig. 116) distinguishes itself by the fact that absorption and biological degradation occur not in separate devices, but in a single plate column [355], [356]. The required bioreactor volume is accommodated on the plates of the column. This concept, which has already proven its worth on a large scale, is characterized by compact construction, high elimination capacity, and a good space–time yield.

3.2.4. Costs and Benefits

Specific investment costs for a biofilter plant (without taking waste-gas collection into account) are estimated at ca. € 230/m^2 for a large facility (ca. 1000 m^2) and as much as ca. € 500/m^2 for a small facility (ca. 100 m^2) [332]. The operating costs associated with a biofilter plant are determined chiefly by the energy costs for fans and waste-air humidification (ca. 1.8–2.5 kWh/1000 m^3 of exhaust air). Costs related to personnel, maintenance, biomass replenishment and exchange, and water must also be taken into account. Figure 117 illustrates the effect on specific operating costs of the waste-air volumetric flow rate. In the waste-treatment sector, where it usually becomes necessary to treat quantities of waste-air exceeding 3000 m^3/h, operating costs are in the range of ca. 0.40–0.65 DM/1000 m^3 of waste air [357].

Figure 117. Operating costs associated with a biofilter plant, including costs for energy, personnel, water, compost, and maintenance
(1 DM = 1.95583 €)

Investment costs of ca. € 5–10 per m^3/h of waste-air capacity have been cited in conjunction with bioscrubbers. The corresponding operating costs are in the range € 0.08–0.18/1000 m^3 of waste air. In this context energy costs account for 80–90 % of the overall expenditures [358].

The fraction of organic emissions for which biological waste-gas purification systems are appropriate, taking all factors into account, has been estimated for Germany to represent about

10 % of total emissions [331]. The potential for such biological processes applies especially to waste air containing very low concentrations of odorous substances or solvents. Compared with catalytic and thermal processes, the biological processes offer the advantage that compounds present in the ppm range can be removed in an economically justifiable way provided they are water-soluble and sufficiently readily biodegradable.

4. Chemical Wastewater Treatment

Quite apart from much older methods for the oxidative and reductive elimination of wastewater components in the course of microbial metabolism, processes have been developed especially in the last twenty years that utilize chemical reactions directly for the degradation of water contaminants. Some have been developed to the point of technical maturity, and without exception these are oxidative processes (→ Oxidation, Chap. 4.4.2., → Oxidation, Chap. 5.2.1.).

The active oxidizing agents are oxygen- containing radicals, in the vast majority of cases the radical $H-O^{\bullet}$. The oxidizing agents actually introduced are usually air, oxygen, hydrogen peroxide, or ozone. Process-engineering characteristics distinguishing the individual methods vary quite considerably. What differentiates one process from another, and distinguishes all of these approaches from the microbial route, is a consequence largely of the nature of the wastewater itself and the extent to which its components should or must be degraded. It should also be noted that advantage is sometimes taken of several either direct chemical or biochemical methods, as well as combinations of the two together.

The generally more drastic reaction conditions or more aggressive reactants associated with a purely chemical method, and the often higher degradation rates achieved, lead easily to the impression that direct chemical methods are inevitably superior to biochemical methods. This is not necessarily the case, however. Material degradation is first and foremost a kinetic problem, and reaction mechanisms and catalysis play decisive roles [359–361]. To describe a substance as "not degradable" is basically an unwarranted oversimplification, because it implies that "degradability" is a fixed property of a substance, whereas it is in fact a matter of behavior; i.e., some degradation will indeed occur, but at a rate that is unacceptably low. In drawing any methodological comparison, various direct chemical methods must be taken into account, and especially from the following points of view [359–364]:

1) Energy costs – and not only with regard to requisite temperature levels, but also the required duration of action and any energy expenditures associated with separation and enrichment steps, especially in the case of dilute wastewater.
2) Irregular waste flows and how to cope with peak volumes or concentrations. Microbial processes function best when volumes and concentrations are relatively constant. Large fluctuations, especially toward higher values, can often be managed with the aid of subsequent or parallel chemical process steps.
3) Mixed wastewater and the separation of partial ("split") streams containing slowly degradable or interfering wastewater components [359], [360], [364]. Major grounds for the separation and individualized treatment of specific production wastewater streams include the following:
   a) A certain partial stream is characterized by high volume and the presence of contaminants amenable to degradation by means of the simple and inexpensive low-pressure wet-oxidation process (Section 4.4.1), resulting in a secondary wastewater suitable for introduction into a central biochemical wastewater-treatment plant.
   b) A partial stream contains wastewater components that degrade only slowly, suggesting that high-pressure wet oxidation (Section 4.4.2) might be feasible. This process is quite elaborate and involves relatively high operating costs, so a more economical alternative might be to pursue chemical degradation only up to the point of suitable fragmentation, assigning the responsibility for further degradation, as above, to a central biochemical wastewater-treatment plant.

c) A partial stream contains such a high level of salts that a cell culture would no longer be capable of functioning. Wet oxidation on the other hand might not be feasible either if in the case of certain salt-like companion substances the threat of corrosion rules out both low- and high-pressure oxidation. Such a case could be dealt with (after appropriate concentration) only by strictly thermal oxidation based on combustion (see Chap. 6).

Generally speaking, chemical treatment is restricted to special wastewaters characterized by components that are degraded too slowly in conventional waste-treatment plants or that interfere with the biochemical degradation of other substances. Chemical waste degradation processes then open to consideration include the following, listed in order of increasing operating temperature (and pressure):

1) Atmospheric-pressure wet oxidation by means of hydrogen peroxide, ozone, or air, with iron oxide or titanium dioxide as catalyst.
2) Low-pressure wet oxidation with air, based on an iron/quinone catalyst.
3) High-pressure wet oxidation with air, using copper as the catalyst.
4) Thermal oxidation; i.e., evaporation of water and combustion of the residue.

There is no such thing as a single "best" process, one clearly characterized by an ecological maximum and economic minimum. What is instead required is extensive experimental investigation to establish the limits and possibilities associated with each individual case, thereby providing a sound basis for meaningful comparisons. The question of how one should proceed with a particular wastewater source can then be answered reliably.

Thermal processes must generally be ruled out in cases involving low concentrations of degradable substances because of excessively high specific energy costs per unit volume. The use of hydrogen peroxide is often advantageous here, especially if the substances in question accumulate on an irregular basis. With higher contaminant concentrations, either high-pressure or low-pressure wet oxidation can be implemented. Evaporation followed by combustion becomes the method of choice if there is the added complication of high concentrations of inorganic salts. Wastewater of this type is derived largely from the chemical and materials-processing industries.

4.1. Oxidative Degradation by Hydrogen Peroxide

The direct oxidation of organic compounds by hydrogen peroxide under acidic conditions is a well-known but relatively seldom-employed process. The oxidation potential of H_2O_2 can be increased above that of ozone through catalysis, usually with Fe^{2+}. Oxidation with hydrogen peroxide was investigated as early as 1968 in conjunction with the treatment of municipal sewage [365] and wastewater from industrial production [366–368], especially effluents containing sulfur and phenols [359–372]. Successful hydrogen-peroxide treatment of wastewater from hardening plants [373] and tanneries [374] has also been described.

The special advantage of this process is that the technological effort required is small, an especially positive factor in the case of dilute wastewater (i.e., < 10 g COD/L). Nonbiochemical treatment is of special importance for wastewater fractions with low concentrations of contaminants, because the correspondingly large volumes determine the size of the required treatment facility, and thermal processes are excluded because of the enormity of the associated energy requirement.

Oxidation with H_2O_2 proceeds at atmospheric pressure and room temperature within 60–90 min. Hydrogen peroxide is not toxic, is easy to handle, and decomposes into the environmental products oxygen and water. Large-scale use of this otherwise virtually universal oxidizing agent is restricted by the high price of H_2O_2 itself, together with the fact that although self-decomposition proceeds with the formation of oxygen, the resulting oxygen contributes almost nothing to the oxidation process.

Hydrogen peroxide is not merely an oxygen-transfer agent that facilitates work in a homogeneous aqueous phase; indeed, one should make every effort to avoid conditions favoring the self-decomposition of hydrogen peroxide, i.e.:

$$H_2O_2 \longrightarrow H_2O + 1/2\,O_2$$

More to the point is the fact that catalysis by iron (molar ratio $H_2O_2 : Fe^{2+} = 15:1$, pH = 3.0), leads – as in the reaction of the Fenton reagent – to the formation of the $H-O^{\bullet}$ radicals, and it is these that constitute the actual oxidizing agent.

The redox potential E_0 for the reaction sequence

$$H_2O_2 \longrightarrow HO^+ + HO^-$$

$$Fe^{2+} + HO^+ \longrightarrow Fe^{3+} + HO^{\bullet}$$

$$HO^{\bullet} + H^+ + e^- \longrightarrow H_2O$$

has been determined to be 2.28 V [359], [375]. For the analogous reaction with ozone the redox potential is 0.21 V lower:

$$O_3 + 2\,H^+ + 2\,e^- \longrightarrow H_2O + O_2 \; (E_0 = 2.07\,V)$$

In the case of substances that oxidize only slowly even under these conditions, or via oxidation chains starting from them, it has been observed that self-decomposition of H_2O_2 – which is of no value for COD degradation – becomes appreciable. It is therefore necessary to establish the extent of utilization of introduced H_2O_2, and to compare this with the applied dosage in that particular case. The dosage should then be decreased until a utilization of nearly 100 % is achieved [375]. If a dosage is calculated based on the stoichiometry corresponding to complete oxidation all the way to CO_2, an almost equivalent COD degradation can usually be achieved with 60 % of the calculated dose, resulting in almost 100 % utilization of the added H_2O_2 [375].

The heat of reaction has also been determined under these conditions, leading to the following values established with a flow calorimeter (isothermal) [366]:

$$Q_1 = 4.59\,\text{cal/mg COD} \triangleq 19.22\,\text{J/mg COD} \; (\pm 3\,\%)$$

$$Q_2 = 2.48\,\text{cal/mg } H_2O_2 \triangleq 10.39\,\text{J/mg } H_2O_2 \; (\pm 4\,\%)$$

The extent to which different classes of substances differ in their behavior is illustrated by the data in Table 10. From an economic standpoint, the selected conditions in this study were appropriate only for the last two substances listed. The process can be regarded as nonspecific with respect to the various classes of organic substances typically encountered in wastewater. It also shows little dependence on the salt load.

The degradation of more than 100 individual compounds as well as authentic industrial wastewaters has been described [366], [375]. As a result of adsorption on flocculated material during the neutralization step the process leads to an effective reduction of COD roughly 10 – 15 % greater than the level of true degradation.

The process can be operated continuously in the form of a cascade (Fig. 118). On a pilot-plant scale ($\leq$ 500 L) the residence time is 60 – 90 min with a dosage of 20 – 80 % H_2O_2/COD. Partial oxidation with maximum utilization of H_2O_2 is pursued only to the point at which the wastewater can be subjected to subsequent degradation in a biological wastewater-treatment plant without impairing biochemical processes there. The type and level of salts present is of some importance, even though the actual oxidation with H_2O_2 is largely insensitive to salts [376]. Considering only the COD value of the wastewater, partial oxidation with H_2O_2 is still technically feasible with dilute effluents in the concentration range 0.5 – 10 g COD/L, where thermal processes must be excluded because of the associated energy demand.

Figure 118. System for the continuous treatment of wastewater with H_2O_2

Radical formation based on hydrogen peroxide has also been achieved by UV irradiation for wastewater-treatment purposes [362].

Table 10. COD elimination of various substances as a function of H_2O_2 utilization

Substance	Dosage H_2O_2/COD, % of stoichiometric amount	COD elimination, % of initial value	H_2O_2 utilization, %
Morpholine	100	20	20
2-Aminoethanol	100	37	37
Diethyleneglycol	100	45	45
Polyethyleneglycol	100	35	35
Hexamethylenetetramine	100	32	32
2,4-Difluoro-5-chloro-6-methylpyrimidine	100	30	30
Phenyltrifluoroethylcarbamide	80	75	94
Ammonium trifluoroethyldithiocarbamate	80	79	99

4.2. Oxidative Degradation by Ozone

Use of ozone for the oxidative elimination of wastewater components has also been known for a long time [377]. Ozone was used even earlier for the sterilization of air and the treatment of drinking water. Its effectiveness is highly dependent on the pH (Fig. 119), and is based essentially on two mechanisms:

Figure 119. Ozonization of *p*-chlorophenol at an initial concentration C_0 of 250 mg/L (TOC = 140 mg/L, COD = 420 mg/L, AOX = 69.0 mg/L)
a) TOC; b) COD; c) AOX

1) So-called direct oxidation occurs under acidic conditions. This is a fairly slow process, but the conversion can be accelerated greatly if the energy necessary for radical formation is provided in the form of UV light from a Hg low-pressure radiation source [378–381].

$$O_3 \xrightarrow{h\nu} O^{\bullet} + O_2$$
$$O^{\bullet} + H_2O \longrightarrow H_2O_2$$
$$H_2O_2 \xrightarrow{h\nu} 2\,HO^{\bullet}$$

2) Alkaline oxidation also takes place via the intermediate formation of hydroxyl radicals [379]:

$$O_3 + HO^- \longrightarrow HO_2^- + O_2$$

$$HO_2^- + O_3 \longrightarrow {}^{\bullet}O_2^- + O_2 + HO^{\bullet}$$

$$H_2O + O_3 + {}^{\bullet}O_2^- \longrightarrow HO^- + 2\,O_2 + HO^{\bullet}$$

Ozonization of organic halogen compounds leads to both inorganic halide (from dehalogenation at C–Cl bonds) [377], [382] and the ensuing formation of new organic halides [381].

The formation of organic halides has also been detected in wastewater containing a combination of chlorine-free organic materials and inorganic halides originating from the accompanying salt load [381], [383], [384]. Compounds formed in this way generally reflect the presence of oxidizing agents, especially ozone or hydrogen peroxide.

Figure 120. Ozonization of phenol (176 mg/L) in the presence of chloride ion
a) 2.0 g/L Cl^-; b) 2.0 g/L Cl^- + UV; c) 50.0 g/L Cl^-; d) 50.0 g/L Cl^- + UV

In this system, oxidative degradation of C–H and C–C bonds and the formation of C–Hal bonds in the presence of the appropriate salts is strongly pH dependent (see Fig. 120). Radical reactions produce the intermediate hypochlorite [383], which in alkaline medium also acts as an

oxidizing agent. Chlorination at carbon is clearly apparent under acidic conditions, as implied by an equilibrium shift in the system

$$Cl_2 + H_2O \rightleftharpoons HOCl + HCl$$

This effect is even more pronounced in the case of the higher halides (Fig. 121) [383], [385], [386], as shown by the following data on C–Hal formation in conjunction with TOC oxidation:

Halide	Threshold pH
Chloride	< 5
Bromide	< 10
Iodide	< 12

Oxidative cleavage predominates in all three cases at a pH > 4.

Figure 121. Ozonization of phenol (176 mg/L) in the presence of bromide and iodide ions
a) 500 mg/L I^-; b) 500 mg/L Br^-

The oxidative treatment of wastewater containing salts requires the prevention of simultaneous and persistent halogenation. A high chloride content must be anticipated in seepage water from landfills and in certain effluent streams derived from production lines in chemical processing plants.

Bromide in drinking water leads to the formation of organobromine compounds upon ozonization [385]. Special measures must be instituted in dealing with bromide- and iodide-containing wastewaters derived from the processing of color negative films and the production of printing plates [381]. In the case of iodide- containing wastewater it is useful to remove the iodide prior to oxidation of other constituents. With bromide- containing wastewaters it is possible to degrade the adsorbable organic halide (AOX) formed in situ during the course of oxidation by introducing an excess of oxidizing agent.

Radicals derived from natural ozone, and from natural, extracellular sources of hydrogen peroxide in the soil, especially the hydroxyl radical $H-O^{\bullet}$ [387–389], also produce halogenated intermediates in the presence of ubiquitous salts, including halogenated metabolites. Some of the latter are intermediate products with a limited lifetime in the mineralization process, whereas others are persistent excretion products in the form of humic acids with halogenated aromatic groups. Similar processes are observed in the ocean and in inland waters.

Corresponding process engineering in industry (i.e., oxidative degradation reactions with the simultaneous formation of intermediate organic halogen derivatives) has so far not been reported, although oxidative degradations in the form of natural decomposition and decay induced by natural oxygen sources together with biochemical catalysts (e.g., oxidases, peroxidases) have been simulated in the laboratory [389]. Specific proposals were developed in conjunction with this study for the industrially very important degradation of lignin in the wastewater released from paper and pulp mills.

Figure 122. Schematic representation of a thin-film fixed-bed reactor for solar detoxification
a) Wastewater source; b) Pump; c) Catalytic surface; d) Effluent; e) Recirculation (optional)

4.3. Photocatalysis in Oxidative Degradation by Air

Semiconductor catalysts such as the oxides of titanium, iron, or zinc, together with atmospheric oxygen as the oxidizing agent and sunlight as a source of the requisite activation energy [362], [390] constitute systems for the treatment of dilute wastewater. These systems have already

been investigated in the context of photochemical degradation of organic substances in the atmosphere (→ Air, Chap. 8.) [391], [392].

Apart from studies involving individual substances [393–395], the behavior of actual wastewaters [396] has also been investigated in a thin-film fixed-bed reactor (Fig. 122), including groundwater, seepage water, influents to biochemical wastewater-treatment plants, and the corresponding effluents [362]. A decrease in TOC is observed even under neutral conditions, and at a pH of 3 or less the residual TOC may be as little as 30 % of the initial value (Fig. 123).

Figure 123. Relative TOC content as a function of irradiation time in the photocatalytic treatment of seepage water (volume = 1,4 L; $[TiO_2] = 1$ g/L; $[H_2O_2]^0 \approx 1500$ mg/L; $[TOC]^0 \approx 320$ mg/L; $[COD]^0 \approx 900$ mg/L; $[BOD_5]^0 \approx 10$ mg/L; O_2 flow rate ≈ 35 L/h; $T = 20-23$ °C; UV irradiation ≈ 50 W)

□ pH 11; ▲ pH 7; ○ pH 5; ■ pH 3

The early stages of the process are characterized by an increase in biological oxygen demand, with the concurrent formation of biodegradable fragments (Fig. 124).

A consideration of the associated energy factors shows that titanium dioxide absorbs light only at wavelengths below 390 nm because of its relatively large band gap of 3.2 eV. Accessible sunlight with a radiant power of 20 – 30 W/m^2 in the wavelength range 300 – 400 nm makes available 0.2 – 0.3 photons per m^2 per h. Quantum yields of 0.1 – 10 % have been reported at TiO_2 surfaces. Assuming an average quantum yield of 1 %, this energy source would suffice for the degradation of 2 – 3 mmol of wastewater components per square meter of surface area per hour. For substances with molecular masses of ca. 100, present in concentrations of ca. 1 mg/kg, the potential wastewater throughput would be 200 –300 L/h for an absorption surface area of one square meter. Lamp panels equipped with standard fluorescent lamps of the type developed for tanning benches have also been used as sources of near-UV radiation. The corresponding degradation reactions proceed more rapidly with hydrogen peroxide as a sole or supplementary source of oxygen.

Variants such as parabolic channel reactors have been found to be much less effective than thin-film fixed-bed reactors [362]. Such chemical variants as hydrogen peroxide in conjunction with mixed oxides based on Fe(III)/Ti(IV) have led to better utilization of the available visible light, because α-Fe_2O_3 absorbs at wavelengths under 540 nm [362], [397]. Photoreactivity has been found to increase in the presence of mixed oxides of this type as a result not only of photooxidation but also photoaddition [398], which may prove to be of some importance in the context of degradation intermediates.

4.4. Wet Oxidation by Oxygen Sources in the Aqueous Phase

Oxidative degradation of wastewater components by means of air or oxygen under pressure and at elevated temperature is generally referred to as "wet oxidation." The essential features of this process have been known since 1912, and wet oxidation in the form of the Zimpro process has been in use since 1958 [399], mainly

in the treatment of wastewater from the pulp industry and municipalities [400–422]. The number of such plants currently in operation worldwide is rather small, but of all the non-biological wastewater treatment processes, wet oxidation is at present the most important. As a result of its ready adaptability to a wide variety of conditions relevant to the wastewater problems of both industry and municipalities, this process is attracting increasing interest.

Apart from its use in the oxidation of inorganic components, wet oxidation is also being implemented increasingly for the oxidation of organic constituents in wastewater, although the requisite temperatures and pressures are significantly higher than in the otherwise customary approach of clarification-sludge conditioning [359], [366]. As with other alternative processes, the advantage of wet oxidation lies in its potential for the treatment of partial wastewater streams containing components that degrade only slowly in a biological wastewater-treatment plant. Another advantage is the possibility of dealing with large quantities of wastewater containing contaminants of high concentrations, often with reasonable investment and operating costs. Characteristics of the process include some tolerance for salt-like companion substances, slightly acidic operating conditions, and catalysis by heavy metals, primarily Fe(II,III). Assuming complete degradation of the starting materials, the reaction products from oxidation of compounds containing the elements carbon (organic), hydrogen, nitrogen, sulfur, phosphorus, and chlorine are the corresponding mineralization products: CO, CO_2, H_2O, N_2, SO_4^{2-}, PO_4^{3-}, Cl^-, and NH_4^+. Operating experience with such systems has been accumulating in the chemical industry since 1978, when the first of many wet-oxidation plants installed by Bayer first went into operation at facilities in Germany and elsewhere.

With air or oxygen itself as the oxygen source, a pressure in excess of 0.4 MPa, and temperatures > 60 °C, pronounced degradation can be achieved for certain classes of compounds. However, with other substance categories even the originally reported higher temperature of 170 – 220 °C proved insufficient for achieving satisfactory degradation rates over short residence times [366], [399].

In order better to assess the potential range of applications for wet oxidation it has proven advantageous to develop two process variants with differing reaction conditions. The corresponding distinctions with respect to temperature and pressure are also associated with important differences in process engineering factors, material considerations, and plant safety requirements. Low-pressure wet oxidation has been the subject of especially extensive development, as a result of which the applicability and potential of the process have been greatly expanded. Based on experience collected to date, a line can be drawn at 200 °C and 0.5 – 2 MPa between low-pressure wet oxidation and high-pressure wet oxidation.

Figure 125. Flow diagram of a wet-oxidation plant for SO_3^{2-}/HSO_3^- - containing wastewater
a) Bubble column; b) Heat exchanger; c) Pumps

4.4.1. Low-Pressure Wet Oxidation

Inorganic substances also count among the oxygen-consuming wastewater components provided they are present in low valence states. Usually this involves reductive sulfur compounds in which sulfur has an oxidation number between − 2 and +4, most often wastewater containing the sulfite – hydrogensulfite system. The oxidation itself proceeds as follows:

$$SO_3^{2-}/HSO_3^- + O_2 \xrightarrow[\text{pH } 1-5]{Fe^{2+/3+}} SO_4^{2-}/HSO_4^-$$

Sulfite/hydrogensulfite-containing wastewater is continuously pumped into an oxidation bubble column by way of a countercurrent heat exchanger. Here it is oxidized by pure oxygen at temperatures between 60 and 100 °C and a pressure of 0.4 – 0.6 MPa to give a sulfate – hydro-

gensulfate mixture (Fig. 125). An aqueous solution of iron sulfate is used as the catalyst. The required oxygen is recirculated by means of a pump-driven ejector.

Provided no inert gases like nitrogen or carbon dioxide are present in the wastewater, no gas will accumulate in the gas space, and no off-gases are evolved. Only additional oxygen necessary for the oxidation must be supplied over the course of time via a pressure holding valve.

This mode of operation makes it possible to respond immediately to fluctuations in the sulfite concentration of the influent without the need for elaborate concentration measurements. The rate of oxidation is highly dependent on pH (Fig. 126). Oxidation is even possible without a catalyst; catalysis with Fe permits a doubling of the throughput.

Figure 126. Influence of pH, temperature, and Fe^{2+} concentration on the rate of oxidation of Na_2SO_3 (p_{O_2} = 0.4 MPa)

○	100	90	50

Numerous processes important in chemical industries utilize sodium sulfide or hydrogen sulfide as a reducing agent. The wastewater that results contains not only sulfide, but also both sulfite and thiosulfate ions. Wastewater of this type is treated in a two-stage wet-oxidation plant like that shown in Figure 127, which operates at a temperature of 120 – 140 °C and a pressure of 0.5 – 0.6 MPa.

Figure 127. Flow diagram of a two-stage facility for the wet oxidation of wastewater containing reductive sulfur compounds

The first stage of such a facility accomplishes the rapid alkaline oxidation of sulfide to thiosulfate:

$$4\,S^{2-} + 3\,O_2 \xrightarrow{OH^-} 2\,S_2O_3^{2-}$$

The second stage operates under acidic conditions, thiosulfate being oxidized to sulfates.

$$S_2O_3^{2-} \xrightarrow{H^+} S^0\ \text{(colloidal)} + SO_3^{2-} \xrightarrow[Fe^{2+/3+}]{\frac{1}{2}O_2} SO_4^{2-}$$

In both cases the oxidizing agent is pure oxygen, recirculated by means of an ejector system.

The oxidation of thiocyanate demands more drastic conditions:

$$SCN^- + 3\,O_2 \xrightarrow[Fe^{2+/3+}]{H^+} SO_4^{2-} + NH_4^+ + CO_2$$

Catalytic amounts of iron will not suffice for this oxidation at 130 – 150 °C; stoichiometric amounts must be used instead. Catalytic amounts are adequate only in the temperature range 180 – 200 °C.

The oxidation of nitrogen-containing inorganic wastewater components is easily achievable with wet oxidation in the case of nitrite or hydrazine. The oxidation of nitrite takes the form

$$NO_2^- + \tfrac{1}{2}\,O_2 \xrightarrow{H^+} NO_3^-$$

so nitrite-containing wastewaters can be treated in the same way as sulfite-containing material

in a single-stage process that evolves no off-gas. The oxidation can be accomplished without a catalyst at 30 – 50 °C. With hydrazine- containing wastewater the oxidation can be represented as

$$N_2H_4 + O_2 \xrightarrow[Fe^{2+/3+}]{H^+} N_2 + 2\,H_2O$$

Nitrogen formed during the process must be removed along with the off-gas from the single-stage wet oxidation. Reaction conditions range from 50 – 120 °C at 0.4 – 0.5 MPa [423].

Organic wastewater components represent a much more fertile field of application. Many problematic wastewater streams arise during the course of syntheses carried out in the aqueous phase, some in separation steps associated with the isolation of intermediates, and others during the isolation and purification of final products. Some of this wastewater contains substances that degrade only very slowly in a biological wastewater-treatment plant, especially certain aromatic derivatives that can be degraded biologically only with difficulty, and then only with special bacterial cultures (see Section 2.1).

The treatment of wastewater containing such aromatic compounds can be accomplished at temperatures below 200 °C in the presence of an appropriate redox catalyst [423]; especially suitable for the purpose is the system quinone ⇌ hydroquinone Fe(II) – Fe(III):

Quinone-forming agents and substances containing partial quinoid structures are also suitable. In the course of the catalytic wet oxidation of aromatic compounds, 60 – 90 % of the carbon is oxidized to CO_2 depending on the nature of the compound and the reaction temperature. Residual organic matter remaining in the wastewater consists chiefly of metabolites like acetic acid and acetone, which are subject to further biological degradation. Organic nitrogen is converted mainly to ammonia.

A time vs. conversion curve (Fig. 128) based on the wet oxidation of phenol (2 g/L, 140 °C, 0.3 MPa, Fe 0.3 g/L, quinone 0.3 g/L, pH 2) reveals this to be a first-order reaction. After a reaction time of 90 min the TOC value is reduced by 70 %; indeed, phenol is no longer detectable by gas chromatography after only 45 min. No phenol oxidation whatsoever is found to occur under otherwise identical conditions in the absence of the catalyst combination.

Figure 128. TOC elimination from a phenol solution by catalytic wet oxidation at 140 °C (see text for details)

Studies based on other aromatic compounds indicate that amino- and hydroxyl-substituted phenols, naphthols, and their analogues are readily degraded by low-pressure oxidation at 120 – 150 °C with Fe – quinone catalysis, whereas sulfo and nitro derivatives are less readily degraded [359], [366], [423]. Most other compounds require an operating temperature of 180 – 190 °C.

When wastewater derived from the production of anthraquinone dyes is oxidized in a multistage bubble column (Fig. 129) at ca. 190 °C and 1.6 – 1.8 MPa, a COD reduction of 85 % is typically achieved. As much as 90 % of what remains is subject to subsequent degradation in a biological waste-treatment plant. Taken together these results amount to a COD reduction of 98 % in the combined process, equivalent to almost

complete degradation. Wastewater of this type inevitably contains quinone-forming agents at a level high enough such that the further addition of quinone is unnecessary. In other cases it frequently suffices to introduce alkali-treated brown coal as a quinone-forming agent.

Figure 129. Flow diagram of a Loprox facility operated at 120 – 200 °C and 0.3 – 2.0 MPa with a retention time < 3 h

The degradation of aromatics is of great importance not only because a considerable fraction of chemical wastewater is derived from the production and further processing of aromatic compounds, but also because operators of waste-treatment plants are becoming increasingly interested in wet oxidation as an aid to the disposal of clarification sludge. Like many types of soil, however, clarification sludge always contains humic acids formed in the ubiquitous presence of sodium chloride, and characterized by aromatic nuclei bearing 1 – 3 atoms of chlorine [389].

With respect to aliphatic compounds, methanol and many carboxylic acids prove to be only slowly degradable by low-pressure wet oxidation, and in the case of amino compounds all that is observed is cleavage of the amino groups. Nevertheless, even this modest change results in a clear improvement in biodegradability.

The process of low-pressure wet oxidation is in fact rather substance-specific. Given that the extent of COD reduction for a wide variety of organic compounds ranges from 15 – 90 %, a targeted investigation is required to establish whether the process is suitable for use in a specific case. If tests are conducted on the basis of a batch operation it is necessary to take into account the fact that both pH and redox potential may shift under the test conditions. In a continuous operation various measures can be implemented to ensure that the reaction conditions remain constant at their optimal values.

One adaptation of wet oxidation with wide applicability, especially in conjunction with biological waste treatment, is the Loprox (Low-Pressure Oxidation, see Fig. 129) process developed by Bayer. This process accomplishes partial oxidation of a range of compounds that are only slowly biodegradable, and it is thus useful for preparation of a split wastewater stream prior to its introduction into a conventional waste-treatment plant [424]. Experience has now been collected from Loprox plants over a period of more than 15 years, including plants of various sizes (with wastewater throughputs of 4 – 60 m^3/h) [425], [426]. Residence time in the pressure reactor is 1 – 3 h. The preferred influent is wastewater with a COD range of 5 – 50 g/L. The oxidation reaction is exothermic, with the temperature rising during the course of degradation. A wastewater COD value of 6 – 8 g/L is sufficient to permit oxidation to proceed autothermically. Once the plant has been brought up to temperature no further input of heat energy is required.

Based on data from wastewater contaminated with difficult to degrade chloroaromatics, it is apparent that the COD and the AOX both decrease with increasing reaction temperature during the course of the Loprox process (Fig. 130), and that the decrease in AOX values is usually more rapid and of greater magnitude than the decrease in COD. The BOD_5 value increases simultaneoulsy.

Figure 130. Typical course of reaction in the Bayer Loprox process
• COD; ▲ AOX; ■ BOD_5; ▼ BOD/COD

At a reaction temperature of 190 °C the AOX falls by more than 90 %, and the COD by more than 75 %. The ratio BOD_5/COD increases from less than 0.1 to above 0.5, a value characteristic of a readily biodegradable wastewater [424–426].

The conditions of the reaction impose certain restrictions on materials that can be used for the hot parts of the plant. Equipment that is enamelled or lined with PTFE is suitable for operating temperatures < 160 °C. Metal parts must be fabricated from titanium or its alloys with palladium for temperatures ≤ 200 °C. This also ensures corrosion resistance at high chloride-ion concentration. However, fluoride ion at a concentration > 10 ppm must be removed by precipitation with Ca(II) and subsequent filtration. Apart from the quantity of wastewater subject to treatment, operating costs also depend heavily on the reaction temperature. For a single-stage plant these costs range from ca. € 2.6/m^3 at 100 °C to € 10 – 20/m^3 at 200 °C [423], [427].

The applicability of the process in both industrial and municipal settings is largely dependent on the availability of a suitable process and disposal combination [426–429]. Several illustrative examples are examined in detail below.

Wastewater from Pulp Production. The Loprox process makes it possible under fairly mild reaction conditions to partially oxidize long- chain wastewater components to such an extent that they become biodegradable. Crude wastewater from pulp prodution usually has a COD of 20 – 30 g/L, of which at most 50 % represents biodegradable substances. At a temperature of ca. 150 °C and a residence time of one hour, the Loprox treatment results in a reduction in the COD to 9 g/L and a marked improvement in the biodegradability of the outflow based on a single-stage mode of operation. The residual COD can be reduced further to the extent of 92 % by subsequent biological treatment, resulting in an overall COD reduction > 97 %.

Clarification Sludge from a Biological Wastewater-Treatment Plant. Excess organic sludge is separated by sedimentation in the course of final clarification. It is then concentrated in a screen-belt drum to a solids content of ca. 5 % for subsequent degradation in the Loprox process. At a reaction temperature of 190 °C only 10 % of the starting solids remain. These solids consist mainly of mineral components that can be easily separated by sedimentation and then dewatered. Sludge destined for final disposal is thus reduced to 6 – 7 % of the amount that would be generated in a conventional operation.

Combination Disposal Networks in the Context of Chemical Plants. Wastewater treatment at large chemical plants normally occurs in centralized treatment facilities following decentralized pretreatment. The central facility usually consists of a neutralization stage, a preclarification stage, and an aerobic biological wastewater-treatment system with final clarification (see Section 2.1.4). Inclusion of a Loprox plant [428–430] facilitates the handling of problematic split streams from specific production areas as well as from the disposal area itself (Fig. 131). In one particular case, a split stream with a COD concentration of 1.8 g/L, too dilute for direct inflow into a wet-oxidation system, is subjected to a preatreatment consisting of precipitation and flocculation. The resulting concentrate is fed into the Loprox wet-oxidation stage (c), and the overflow into the biological clarification stage (f). The wet-oxidation facility simultaneously receives split streams rated at 20 m^3/h and 30 g/L COD as well as 10 m^3/h and 8 g/L COD, along with concentrated excess sludge from the biological clarification stage. Inorganic matter from

the sludge residue after wet oxidation together with the iron catalyst is discharged, dewatered, and placed into the waste depository. Wastewater subjected to this pretreatment is pumped directly into the biological clarification stage. Coupling the process in this way offers many advantages with respect to both disposition and operation. Nevertheless, the COD cycle associated with clarification-sludge oxidation requires the introduction of 20 % more oxygen into the biological clarification stage than would be the case in a conventional operation.

Split Pretreatment in Conjunction with Dye Manufacture. A two-stage Loprox plant with a throughput of 20 m^3/h is used by Bayer to oxidize primarily inorganic reductive sulfur compounds at a temperature of 120 – 140 °C and a pressure of 0.6 MPa. The pH is subsequently adjusted to a value of 1 – 2 by the addition of sulfuric acid, and a second oxidation is performed in a separate stage at 140 °C in the presence of a catalyst. At the time this process was instituted (1982) it utilized for the second stage the largest one-piece enamel tower ever built, with a height of 10.5 m and a diameter of 1.8 m (Fig. 132).

Figure 132. Two-stage Loprox unit for the pretreatment of 20 m^3/h of wastewater from dye production at the Bayer plant in Leverkusen, Germany

Split Pretreatment in the Production of Organic Intermediates. Using a facility with the same throughput as above but a single-stage mode of operation at 190 °C and 2 MPa it is possible to achieve a chemical wastewater COD reduction of 85 % by wet oxidation, followed by a further 90 % reduction in the biological clarification step, for a total reduction of 98 %. The single-stage column was lined with titanium because of an anticipated chloride content as high as 6 % in the inflow.

Split Pretreatment for Wastewater from Pharmaceutical Production. Wet oxidation proceeds in this case with a throughput of ca. 4 m^3/h at an operating temperature of ca. 160 °C in a two-stage plant with enamel towers, where each tower has a diameter of 1 m and a height of 10 m (Fig. 133). This particular plant was put in operation in 1993.

Figure 133. A Loprox unit for the pretreatment of 4 m^3/h of wastewater from pharmaceutical production at a Bayer subsidiary in La Felguera, Spain

Combination Disposal in a Municipal Wastewater-Treatment Plant. Even if excess sludge that accumulates constantly from aerobic degradation of wastewater components is subsequently degraded further anaerobically (see Sec-

tion 2.2), there still remains a certain amount of sludge to be disposed of. Such sludge typically has a solids content of almost 50 %, 20 to 30 % after dewatering. Until recently sludge of this type was largely consigned to landfill or used for agricultural purposes. In the western part of Germany, for example, only about 10 % of the sludge has been routinely incinerated. Nevertheless, both waste deposition and agricultural use are subject to strict laws and regulations. Combustion is inherently expensive, and it will become more expensive still as increasingly stringent flue-gas restrictions take effect.

Residual sludge disposal by wet oxidation can be conducted as a high-pressure process in the temperature range 250 – 300 °C and at a pressure > 15 MPa, as has been demonstrated by facilities in the United States, Japan, and The Netherlands [430]. Pilot plants have also been operated on the basis of low-pressure wet oxidation for the treatment of both pure biomass derived from fermenters and excess sludge from industrial wastewater-treatment plants [424]. Sludge removed from digester towers is first subjected to wet milling to give particles less than 100 – 200 µm in diameter, after which the mass is adjusted to a pH of 2 and subjected to the Loprox process in the form of a material with a dry-weight solids content of 12 – 15 % (Fig. 134).

The reactor itself is a bubble column without internal fittings, in which the sludge is brought into contact with pure oxygen at 190 °C and 2 MPa over the course of a residence time of 2 – 3 h. It is ordinarily not necessary to add mixed catalyst, because sludge of this type usually contains sufficient amounts of both iron and quinoid substances. After cooling and expansion, solids separation is accomplished by means of filter presses or decanters. The remaining sludge is almost entirely inorganic, and it can easily be dewatered to less than 50 % dry matter. The organic content will have been reduced by about 85 %; almost of the original organic carbon is converted to CO_2, while 1/3 is returned to the biological clarification stage in the form of readily degradable wastewater. Most of the nitrogen originally present resides in this return flow as ammonium ion. If the biological clarification stage includes nitrification, this NH_4^+ is degraded here; otherwise it is eliminated by stripping and subsequent reuse. The ammonia-free return flow from the Loprox process can be utilized as a carbon source and fed directly into the denitrification step of the biological clarification stage [426].

Communities hosting a large number of small and medium-sized factories often encounter problems with poorly degradable wastewater derived from industrial production. In many cases the quantities of waste generated are rather small, and economically viable pretreatment processes might not exist. It has been proposed that such problematic wastewater might be transported in tank trucks to a municipal Loprox plant (Fig. 134) [426]. Addition of a catalyst would not be required, because sufficient catalytic matter is present in the clarification sludge. Experience [426], [427] suggests that current specific operating costs for the treatment of excess sludge from a waste-treatment plant amount to about DM 250 – 350 per ton of dry matter. In an average situation it is possible in this way to achieve a 75 % reduction in sludge volume and an 85 % reduction in the weight of organic dry matter.

Decontamination of Dredger Sludge and Soil. Low-pressure wet oxidation has been used successfully in the treatment of dredger sludge from harbors [426]. The contamination in this case is due mainly to mineral oils and heavy metals. The solids are classified according to particle size directly on the dredging vessels with the aid of wet- cyclone classifiers. Most of the organic contamination is associated with the finest components (< 0.5 mm in diameter). These consist largely of petroleum products, polycyclic aromatic hydrocarbons (PAHs), and chlorinated hydrocarbons. The situation is similar with contaminated soil derived from ground washing. The organic components can be eliminated almost entirely subsequent to Loprox treatment. Thus, an analysis (Table 11) covering the 16 compounds on the United States Environmental Protection Agency (EPA) Register for PAHs shows that more than 99 % of the material in question is destroyed. After separation of the oxidatively treated solids, heavy metals that pass into solution during acidic oxidation are precipitated by the addition of alkali, filtered, and disposed of separately.

4.4.2. Oxidation by Nitric Acid

Nitric acid and its salts have been used as a source of oxygen at the borderline between high- and low-pressure wet oxidation [431]. For TOC degradation of wastewater the preferred reaction temperature is in the range 180 – 220 °C. Ammonia is converted to nitrogen. Here, too, the oxidation can be carried out partially and subsequently completed in a biological clarification stage.

4.4.3. High-Pressure Wet Oxidation

With some types of wastewater associated with dye manufacture or the further processing of organic intermediates, the level of degradation achievable in low-pressure wet oxidation is insufficient. Much more severe reaction conditions are required to attain satisfactory results. The problem is aggravated by the fact that accompanying inorganic salts (which need not in themselves represent an environmental or material problem) become extremely corrosive under the conditions of high-pressure wet oxidation, leading to serious problems with construction materials. The reaction temperature is inevitably 280 °C, and the most important parameters are the pH and the nature of the catalysts. Depending on the situation, either of two forms of high-pressure wet oxidation may be considered:

1) An alkaline procedure in the absence of heavy-metal catalysts like iron and copper (which would precipitate under these conditions).
2) An acidic process that does take advantage of heavy-metal catalysis, with special attention to the materials problem.

The line is drawn between these two approaches essentially on the basis of the concentration of chloride ions, which is in turn a function of the inorganic salt load of companion substances. In the case of wastewater with a chloride concentration ≤ 35 g/L, high-pressure wet oxidation of the acidic type can be conducted in titanium autoclaves, but only in the absence of fluoride ions. Even a low concentration of F^- consistent with the solubility product of CaF_2 is sufficient to initiate corrosion at a pH < 5. Construction materials that have proven suitable include Ti-3.7035 for heated areas and a chloride-resistant stainless steel such as 1.4439 (Antinit, Novonox, Remanit) for cold parts (Fig. 135).

Figure 135. Pilot plant for continuous wastewater treatment with the aid of high-pressure wet oxidation
a) Wastewater; b) Heat exchanger

The following general rules apply to the expected extent of oxidative degradation as a function of classes of substances and reaction conditions [359], [366]:

1) For a given residence time and otherwise comparable conditions, TOC degradation proceeds further under acidic conditions than under alkaline conditions, with the difference becoming less pronounced as the temperature increases (Table 12).
2) Under acidic conditions with a fixed residence time and a temperature $\leq 280\,°C$, TOC degradation can be increased by an average of ca. 12 % by copper catalysis. A Cu(II) concentration of 500 ppm is sufficient. Catalysis loses its importance with increasing temperature. Above 300 °C, a TOC degradation > 90 % is achievable even without heavy-metal catalysis (Table 13).
3) Irrespective of the pH, nitrogen- containing compounds not subject to protonation are degraded to N_2, CO_2, CO, and H_2O. The same applies to protonatable substances under alkaline conditions. In an acidic process, nitrogen compounds that can be protonated are degraded only to ammonia, which undergoes almost no oxidation under these conditions.
4) The COD/BOD ratio after partial oxidation attains a value < 2.5, consistent with the requirements for biodegradable wastewater.

Table 12. Degradation by uncatalyzed high-pressure wet oxidation as a function of pH

An important factor in estimating the costs associated with high-pressure wet oxidation [426], [427] is the concentration of organic wastewater components, especially in view of increasing energy prices. Above 50 g COD/L of wastewater, heat recovered from the enthalpy of oxidation is comparable to the total energy requirement for the process. Several plants are already in operation in various parts of the world [359], [366], [430], [432], [433] (Fig. 136).

Figure 136. Prototype facility for the high-pressure (≤ 20 MPa) wet oxidation of industrial wastewater (cyclohexanone oxidation at the Bayer plant in Uerdingen, Germany)

Table 13. Degradation by uncatalyzed high-pressure wet oxidation as a function of temperature

No.	Contaminant	Concentration, g TOC/L	pH	TOC reduction, % of initial value	
				280 °C	300 °C
1	Aromatic amine	14.6	10	76	76
2	O heterocycle	52	11.5	80	87
3	N heterocycle	14.3	10	85	91
4	Cl- containing sulfonic acid	3.5	1.6	90	93
5	Aminosulfonic acid	23.8	1.4	80	86
6	Azo compound	13.1	10	97	98
7	Aminosulfonic acid	20.2	2.2	87	88
8	Aminopolysulfonic acid	47.6	0.5	64	65
9	Nitro compound	6.0	9.3	93	94
10	Nitrosulfonic acid	14.0	10	76	84
11	N heterocycle	1.1	3.1	77	88
12	Oxy compound	9.2	2.2	75	81
13	Mixed wastewater	11.4	1.9	77	81

The extreme case of a high-pressure wet oxidation occurs at the critical point (i.e., 374 °C and 21.8 MPa), and this has been the subject of investigation on a laboratory scale [434]. Organic wastewater components were found to be almost completely degraded in the course of extremely short residence times. This result may be due to unlimited solubility of the materials in "water" under these conditions. On the other hand, salts precipitate. The most serious problems under these reaction conditions relate to construction materials.

4.5. Hydrogenation

Degradation of wastewater components with the goal of mineralization leads to carbon dioxide and water in the case of the elements carbon, hydrogen, and oxygen. Other elements such as phosphorus and sulfur are oxidized in an analogous way to sulfate and phosphate. In the case of nitrogen, it is the element itself to which the corresponding compounds are to be converted in the mineralization process, a result that cannot be achieved directly by biochemical means (see the discussions of nitrification and denitrifiction in Section 2.1.1.3).

The degradation of nitrates directly to elemental nitrogen is accomplished by using hydrogen. This process is of special interest with respect to avoiding groundwater contamination, or in the pretreatment stage of drinking water preparation. Roughly $^2/_3$ of the nitrate present in crude water can be reduced in this way to nitrogen in the presence of a noble-metal- coated carrier.

Figure 137. Process flow diagram for a wastewater hydrogenation system

Figure 138. Variation in nitrate concentration as a function of time

The so- called KNR process has been implemented in a pilot plant that operates with a

throughput of 3 m^3/h and consistent long-term nitrate degradation at a rate of 45 mg NO_3^-/L (Fig. 137). This would correspond to a degradation of up to 70 kg of nitrate per cubic meter of catalyst per day.

The nitrite concentration in clean effluent water amounts to < 0.1 mg/h, and the nitrate concentration ≤ 17 mg/L (Fig. 138).

5. Physical Wastewater Treatment

5.1. Adsorptive Purification [435–437]

Adsorption processes have been successfully applied in the chemical industry for the purification of water generally, as well as for various solutions and individual wastewater streams.

In the chemical, physical, and biological purification of wastewater dissolved constituents are eliminated not only by use of special absorbents, but also in many cases by adsorption on the surface of undissolved substances already present. Elimination occurring by the latter mechanism cannot be examined separately, so it is simply ascribed to the treatment process as a whole.

The deliberate application of adsorption is always in competition with other chemical, physical, and biological approaches to the purification of wastewater. Ecological and economic considerations are decisive in the choice of any particular process or process combination. The question as to whether adsorption is technically and economically feasible, either alone or in combination with other processes, must be examined separately in each individual case. To this end it is necessary to consider the adsorption phenomenon itself in conjunction with the preparation and regeneration of the adsorbent, since from a process-engineering standpoint the two processes constitute a single entity. In addition, reuse or disposal of materials arising in the course of the process should be taken into account as appropriate.

Adsorption causes dissolved organic wastewater constituents to accumulate at the surface of one or more adsorbents. Adsorption must therefore be regarded as a physical concentration process taking place at a liquid – solid phase boundary, one that competes with other concentration processes occurring at liquid – liquid (extraction or membrane processes) and liquid – gas boundaries (evaporation, distillation, stripping). In the unified examination that follows, it was necessary that some attention also be devoted to such oxidative processes as aerobic biological treatment, chemical oxidation, wet oxidation, and combustion (treated elsewhere in this contribution in detail).

It may be assumed in general that adsorption processes have already established themselves as valuable for dealing with fairly small wastewater streams containing low concentrations of adsorbable substances. Adsorption is especially common in decentralized wastewater treatment, both alone and in combination with other processes.

5.1.1. Adsorption

Dissolved wastewater constituents are potentially subject to attachment at the surfaces of solids. An accumulation of this type is known as *adsorption*, and it is attributable mainly to van der Waals forces, particularly dipole – dipole interaction, though coulombic forces also often play an important role (→ Adsorption). The fixing of a dissolved substance to a sorbent can sometimes lead to an enrichment factor of 10^5 or greater. In most cases the adsorbent – adsorbate mixture must then be worked up in a second processing step. Regeneration of a contaminated sorbent frequently takes advantage of the reverse counterpart to adsorption: *desorption*.

5.1.2. Adsorption Isotherms

The equilibrium state that is established after a sufficient amount of time has elapsed defines the equilibrium concentration of a solute in a liquid and the loading of an adsorbent. This state can be described in terms of so-called *adsorption isotherms* (→ Adsorption, Chap. 4.). An isotherm is applicable only to a specific, defined temperature, although the influence of temperature is very small in liquid – solid systems in contrast to gas – solid systems. The curves themselves are usually determined empirically, but their shape can also be described mathematically.

Langmuir Isotherms. One of the first attempts at developing an isotherm equation was reported by LANGMUIR (1918), who was concerned originally with the adsorption of gases, basing his work on methods of statistical thermodynamics. The Langmuir equation assumes the presence of a homogeneous adsorbent surface, and it is therefore valid only to the point of a monomolecular covering of the relevant surface. In general, Langmuir isotherms are described by the equation:

$$X = X_{\mathrm{m}} \frac{C}{b+C}$$

where X = equilibrium loading, X_{m} = loading for monomolecular coverage, C = residual solution concentration remaining after establishment of the adsorption equilibrium, and b = a constant.

Freundlich Isotherm [438]. The isotherm equation proposed by FREUNDLICH as early as 1906 was established empirically. Because of its relatively simple form it is an excellent device for describing adsorption from an aqueous solution:

$$\frac{X}{M} = kc^n$$

where X = amount of adsorbed substance, M = weight of adsorbent used, C = residual concentration remaining after establishment of the adsorption equilibrium, and k and n are constants specific to a given adsorbent – adsorbate mixture.

Plotting this equation in double-logarithmic form [log (X/M) = log $k + n$ log C] produces a straight line, which greatly facilitates practical application of the method (Fig. 139).

Figure 139. Example of a well-behaved Freundlich isotherm

The Langmuir equation is clearly limited to low degrees of loading, whereas in the case of the Freundlich equation there is no formal concentration-dependent limitation to the expression's validity. In practice, however, a flattening of the Freundlich isotherm does become evident with increasing concentration, which means that the Freundlich exponent (n) increases with decreasing concentration. Thus, rigorous application of the Freundlich equation is limited to a rather narrow concentration range.

Isotherms for Multicomponent Mixtures. Multicomponent mixtures are the rule in practical wastewater treatment, and these can be characterized only by such cumulative parameters as COD, AOX, or UV absorbance. Individual substances included in a collective analysis compete for occupation of the available adsorption sites. Since different substances usually have very different adsorption behaviors, the Freundlich isotherms actually obtained in such cases are curved, or even bent at sharp angles (Fig. 140).

Figure 140. Typical non-linear Freundlich isotherms (a, b, c) obtained with different mixtures of solutes

Despite the complications created by isotherms whose course is not straight, the Freundlich isotherm method is frequently used as a way of rapidly acquiring information regarding adsorbability on adsorbents. Moreover, such isotherms make it possible to estimate adsorbent consumption rates as well as the achievability of particular concentration targets.

There have been very many methods proposed for approximating such mixture isotherms mathematically. All of them are based on the ideal adsorbed solution (IAS) theory. According to this theory of the "ideally adsorbable

solution," mixture isotherms can be computed from single-substance data. A standard method in drinking-water treatment for the arithmetic construction of mixture isotherms is based on approximating the comprehensive results in sections. An extensive description of various approaches to a solution is available in et al. [439].

5.1.3. Adsorption Kinetics

The adsorption process comprises a series of diffusion processes that together determine the overall rate of the phenomenon:

1) Transport of a dissolved molecule from solution to the laminar boundary layer of the adsorbent
2) Diffusion through the laminar boundary layer surrounding the adsorbent
3) Grain diffusion into the interior of the pore system all the way to the active centers

Figure 141. Mass-transfer zone in an adsorption filter bed
A) Schematic depiction; B) Typical breakthrough curve

While step (1) generally proceeds rapidly, step (3) is largely responsible for determining the kinetics of the overall process. Grain diffusion depends, among other things, on the relationship between the size of the adsorbate molecules and the pore diameter, but especially on the length of the diffusion path (i.e., the grain size of the adsorbent).

In a fixed-bed absorber with continuous flow, a combination of all the active diffusion processes leads to the development of an *adsorption* or *mass-transfer zone* (Fig. 141 A). As adsorption proceeds, this mass-transfer zone migrates through the adsorbent bed in the direction of flow. When the front reaches the outlet, *breakthrough* of the dissolved substances begins. Figure 141 B shows an example of a typical breakthrough curve.

Figure 142. Operation of two filters (I and II) connected in series
A) Sequence I → II, early in the process; B) Sequence I → II, when filter I is due to be replaced; C) Sequence II → I′, shortly after the replacement of I; D) Sequence II → I′, when filter II is due for replacement

The length of the mass-transfer zone is a key criterion in establishing the optimum adsorber size for a prescribed wastewater stream. For any given starting solution and pore distribution with respect to the adsorbent, the length of this zone depends exclusively on the grain size and the contact time; i.e., on the ratio of the throughput to the adsorbent filling volume. The objective of preliminary experiments conducted in experimental adsorbers with continuous flow is always the adaptation of adsorber particle size to the size

of the mass-transfer zone and its migration rate in order to optimize adsorption efficiency and adsorbent utilization.

In the case of a relatively short mass-transfer zone, a single-stage adsorber can be used, since the ratio of unused adsorbent to the total volume can be small. If the wastewater of interest contains components that produce a long mass-transfer zone it is advisable instead to connect two or more adsorbers in series. The purpose of this arrangement is to ensure virtual saturation of adsorbent in the first reactor before breakthrough is observed at the end of the sequence (Fig. 142 A). After the first adsorber becomes exhausted (Fig. 142 B and D) it is refilled with fresh or regenerated material, or regenerated in situ, at which point it is moved to the last position in the sequence (Fig. 142 C) so that it may assume responsibility for final purification.

In some cases a more sensible solution is to operate two adsorbers in parallel but with staggered operating times, at least so long as the resulting mixture of purified wastewaters meets the necessary criteria. This method of operation is particularly applicable in situations involving extended mass-transfer zones. When the adsorber subject to the largest period of use must be exchanged or regenerated, either the feed stream is throttled temporarily or the remaining adsorber is used alone for a short time assuming it still has sufficient residual capacity to meet the abruptly increased load.

5.1.4. Adsorbents

Potential adsorbents for adsorptive wastewater purification include activated carbon, lignite coke, activated aluminum oxide, adsorber resins [440], and the isopolyacids of iron, aluminum, or silicon. Useful forms of these materials, their fields of application, and possible elimination mechanisms are summarized in Table 14.

Characteristic properties of the adsorbents, such as specific surface areas, pore volumes, and bulk densities, are collected in Table 15. Isopolyacids cannot, however, be characterized according to these parameters, since their properties are influenced by the conditions under which they form in the wastewater.

5.1.5. Adsorption Processes

Adsorption processes can be conducted either batchwise or continuously. In principle they can also be subdivided into *mixing* and *filter* (*percolation*) processes.

The Mixing Process. Mixing is usually used for batchwise wastewater treatment. It is essentially single-stage in nature, since adsorption and adsorbent separation together constitute one processing step. If technical or economic considerations dictate the use of a multistage mixing process, several discrete processing steps must be arranged in series. This usually entails countercurrent flow, but it can also assume a cocurrent form.

The Percolation Process. The percolation process, which normally involves a fixed-bed adsorber, is applicable to the continuous treatment of wastewater. When conducted in a countercurrent mode it is theoretically a multistage process, with effectiveness being a function of filtering speed and residence time.

The Pulse-Bed Process. In the pulse-bed process, which is a special case of continuous percolation, wastewater and adsorbent are both led in countercurrent fashion through the filter. The wastewater awaiting purification flows steadily from below into the adsorber packing. Adsorptively purified wastewater is withdrawn from the top. Adsorbent charging, in the form of either new material or regenerate, occurs at the top of the filter directly onto the filter bed. Contaminated adsorbent is withdrawn through a specially designed lock at the base of the filter, and then treated appropriately.

Prerequisites and Selection Criteria. A prerequisite to the use of adsorption for wastewater purification is complete wetting of the adsorbent surface by water. This is frequently accomplished in special ways prior to adsorption itself.

To avoid clogging of the filter and blockage of the adsorbent active surface, the wastewater subject to treatment must be freed as completely as possible from solids, if necessary through prior filtration.

Table 14. Adsorbents useful in wastewater purification

Adsorbent	Form of use	Fields of Application		Elimination mechanisms
		Organic	Inorganic	
Activated carbon	powdered, granular, or formed	in molecular solution; hydrophobic	in ionic solution, for heavy metals	adsorption (ion exchange)
Lignite coke	granular, powder	in molecular solution; hydrophobic	in ionic solution, for heavy metals	adsorption (ion exchange)
γ-Al_2O_3	granular, powder	in molecular or ionic solution; hydrophobic, hydrophilic	in ionic solution	adsorption, surface precipitation
Adsorber resins	granules	in molecular or ionic solution; hydrophobic, hydrophilic		adsorption, solid solution – extraction
Isopolyacids (formed within the water)	Fe^{3+}, Al^{3+}, Si^{4-} solutions	in molecular or ionic solution; hydrophobic, hydrophilic, dispersed	in ionic solution dispersed	adsorption, precipitation ion exchange, destabilization

Table 15. Properties of important adsorbents

Adsorbent	Form of use	Specific surface area, m^2/g	Pore volume, cm^3/g	Bulk density, g/L
Activated carbon	granular, powder	500 – 1000	0.3 – 0.8	300 – 550
		600 – 1500	0.3 – 1.0	
Lignite coke	granular, powder	200 – 250	< 0.1	ca. 500
γ-Al_2O_3	granular, powder	300 – 350	0.4 – 0.5	700 – 800
Adsorber resins	granules	400 – 1500	porosity 35 – 65 vol %	650 – 700

Table 16. Summary of the features associated with various adsorption processes

Adsorbent	Mixing process	Percolation process	Special techniques
Activated carbon	powder	granular, formed	PACT $*$, countercurrent, falling bed
γ-Al_2O_3	powder	granular	countercurrent, falling bed
Adsorber resins	granules (fine)	–	–
	–	granules	countercurrent
Isopolyacids	Fe^{3+}, Al^{3+} solutions		formation of the adsorbent within the wastewater by pH adjustment;
	Si^{4-} solutions		preliminary precipitation of activated silicic acid
Attendant problems	solid – liquid separation, processing, regeneration, reactivation, waste disposal	regeneration, reactivation, waste disposal	sedimentation, flotation, filtration, extraction, thermal treatment

$*$ PACT = Powdered activated- carbon treatment.

Table 16 offers a survey of the most important adsorbents and their uses in special process applications.

5.1.6. Adsorbent Recovery and Regeneration

Once adsorptive wastewater purification has occurred, the contaminated adsorbents must then be removed from the purified wastewater by one of the standard solid – liquid separation methods (→ Solid – Liquid Separation, Introduction, → Filtration, → Hydrocyclones → Centrifuges, Filtering, → Centrifuges, Sedimenting, → Sedimentation). This is followed by appropriate reprocessing, the purpose of which is either safe disposal of the contaminated adsorbents or (for economic reasons) their preparation for reuse. Some aspects of adsorbent recovery and regeneration have already been noted in Table 16 under the heading "Attendant problems."

In the case of the mixing technique, added powdered adsorbents or isopolyacids formed in the aqueous solution are subsequently separated

by sedimentation, flotation, and/or filtration. In the percolation process, adsorbents are separated from the purified wastewater by filtration and subsequent draining. This dehydration may be carried out either directly in the filter or in some remote location depending on what is to occur next. Countercurrent pulse-bed adsorbers are particularly convenient if external drying is contemplated.

Direct landfill disposal of contaminated adsorbents is subject to numerous restrictions. Important considerations are water content, elutability of the adsorbed substances, and content of organic material subject to decay. For this reason a thermal treatment based on calcining or incineration is frequently carried out. The residues from such treatment can normally be disposed of without difficulty.

In many cases, contaminated adsorbents are reprocessed for purely economic reasons, permitting their subsequent reuse for adsorptive wastewater purification. In the course of such a regeneration, wastewater constituents that have been eliminated by adsorption can also be recovered selectively. This is most often accomplished by extractive regeneration with solvents, or by a change in pH. With thermal regeneration, adsorbed organic materials are simply combusted.

The various adsorbents are subject to specific regeneration processes that take into account the properties of the materials involved and the nature of the corresponding reaction mechanisms.

5.1.6.1. Regeneration of Carbon Adsorbents

In this category only the activated carbons are candidates for regeneration. In the case of lignite coke the associated costs would exceed the price of new material, so spent coke is normally burned after use.

Thermal Reactivation (→ Carbon, Chap. 5.5.). The carbon regeneration process most frequently encountered in practice is thermal reactivation. This is conducted under the same conditions as fresh carbon production: i.e., at 900 – 1000 °C in the presence of water vapor. Thermal reactivation can be divided into four consecutive steps:

1) Evaporation of adhering water and water resident in the pores; in this step, which occurs during the heating phase, readily volatile substances also can be desorbed.
2) With rising temperatures, desorption of higher-boiling substances occurs.
3) Many organic constituents of wastewater can only be desorbed with simultaneous decomposition. This cracking begins to take place above ca. 400 – 500 °C. The process releases mainly CO and CO_2, but some low molecular mass organic cracking products are also released, while decomposition coke is left behind in the pore system.
4) In the last step of the process, above ca. 850 °C, decomposition coke (lustrous coke) is gasified by the water-gas reaction, which reopens the micropores that are very important for adsorption. This largely selective gasification is made possible by the amorphous structure of lustrous coke, since the more orderly activated- carbon structure withstands attack by water vapor by reason of a higher degree of graphitization.

The thermal units employed for reactivation (such as shelved kilns, rotary kilns, or fluidized-bed furnaces) are identical to the furnaces used for the production of fresh activated carbon. For technical reasons, this particular gas – solid reaction is not used for reactivating powdered activated carbons.

Only with very large wastewater streams is it practical to maintain a reactivation plant directly in conjunction with an adsorption facility. Reactivation plants can only be operated economically at throughputs exceeding several tons per day; moreover, high-temperature units of this type should not be subjected to frequent start-up and shutdown. In most cases, therefore, reactivation is carried out elsewhere by the manufacturer, where unavoidable losses can be also compensated for by fresh carbon. A further reason for encouraging large, centrally operated reactivation plants is the complicated problem of off-gas cleaning, which must ensure that all desorbed organic materials are completely combusted, and that inorganic breakdown products such as HCl or SO_2 are eliminated in appropriate ways.

Chemical Regeneration. In practice, chemical regeneration is carried out only in a few special cases where adsorbed substances can be desorbed by a pH change. This is true, for example, with phenols or organic acids, which can be adsorbed in neutral and acidic medium and subsequently desorbed again with alkali (sodium hydroxide solution). Conversely, compounds like aniline can be adsorbed under alkaline conditions and then desorbed from the adsorbent with acids.

Biological Regeneration. Biological regeneration, frequently described in the literature, is in practice also conducted as a separate process step. Often, however, activated carbon colonized with microorganisms is used in such a way that adsorption of pollutants and biodegradation of the adsorbate occur under equilibrium conditions. In this case the activated carbon frequently assumes a buffering role during concentration peaks.

5.1.6.2. Regeneration of Aluminum Oxide

Aluminum oxide contaminated with organic substances is regenerated thermally. In this case the organic substances are oxidized at a temperature of ca. 750 °C in the presence of excess oxygen. Oxidation occurs either directly on the adsorbent surface or after evaporation into the gas phase.

Aluminum oxide contaminated with inorganic substances is regenerated chemically. For example, sorbed phosphate can be eluted with caustic soda solution.

5.1.6.3. Regeneration of Adsorber Resins

Adsorber resins contaminated only with organic substances are always regenerated chemically. The sorbed substances are eluted by such solvents as methanol or acetone, in combination as required with caustic soda solution.

5.1.7. Applications of the Adsorptive Purification of Wastewater

Potential applications involving the various possible adsorbents for wastewater purification are determined on the one hand by the stated purification objectives and on the other by technical and economic considerations. This point will become clearer with the examples that follow.

5.1.7.1. Purification with Activated Carbon [435–437], [441–445]

Activated carbon is useful in the purification of wastewater as a way of removing most of the nonpolar organic compounds that may be present. Adsorption can be called upon to accomplish this task alone, or it may be used in combination with other processes. Technical and economic considerations determine whether a mixing process with carbon powder or percolation with granular or formed carbon is preferable. Activated carbon is used only in exceptional cases for the elimination of heavy-metal ions [441].

Activated carbon is used preferentially for the adsorptive purification of individual wastewater streams from production plants. Adsorption in this context may be used exclusively, or it may be combined with other processes, as in the two-step approach of stripping followed by adsorption. Decentralized water-protection measures (integrated environmental protection) of this type may be warranted for such purposes as water reuse, product recovery, or wastewater purification. However, reuse of wastewater after an adsorptive purification is frequently limited by the accumulation of non-adsorbable organic or inorganic contaminants.

Product recovery by adsorption on activated carbon may prove feasible if the wastewater stream is contaminated mainly with a single organic compound, and if this compound is readily adsorbable and desorbable. Examples worth noting include aniline, which is readily adsorbed from alkaline solution onto activated carbon and then desorbed by acid extraction in the form of an ammonium salt, as well as phenol, which can be correspondingly adsorbed from an acidic solution and desorbed by alkaline extraction as a phenolate salt.

Wastewater purification with activated carbon is especially appropriate whenever it is possible to discharge the treated wastewater directly into a receiving stream, or when activated-carbon treatment is used to remove substances

that would otherwise interfere with subsequent biological processing, perhaps in a centralized wastewater-treatment facility.

One special application is the use of activated carbon in biological treatment systems [442]. Thus, activated carbon is employed in biofilters (Section 3.2) [444] both as a growth surface for microorganisms and as an adsorbent for wastewater constituents. One prerequisite in this case is that the organic constituents be biodegradable. With batch filters the activated carbon is regenerated biologically after adsorption has occurred, whereas with a continuous filter the filter output mut be monitored regularly to assess the rate of biodegradation. Growth surfaces other than adsorbents can also be utilized in biofilters [443]. Powdered activated carbon is often introduced into activated-sludge operations, producing a combination known as the powdered activated-carbon treatment (or PACT) process. It is especially suitable for situations in which small amounts of readily adsorbable substances tend to inhibit biological degradation, substances that are not eliminated by other pretreatment measures in affect. The PACT process has also been considered as a way of adapting existing activation plants to meet overload conditions. In this context the powdered activated carbon serves as a growth surface for the activated sludge, causing the latter to proliferate so that the bioreactor can be operated with a higher biomass concentration. Other powdered substances can be called upon to play a similar role as well, including lignite coke dust (see the description of the PACT process under "Special Process-Engineering Solutions" in Section 2.1.3).

Treatment with activated carbon downstream from a central biological clarification plant is practiced only in exceptional cases, such as for reducing the toxicity of a wastewater effluent toward fish. This particular variant was once considered quite attractive, but it has been found to be subject to serious operational problems. Biological growth on the activated carbon can lead to anoxic conditions, with the resulting mercaptans and hydrogen sulfide constituting a considerable source of odor emission. Serious corrosion problems are also encountered in the filters themselves for related reasons. Downstream adsorption has therefore been abandoned in most cases in favor of appropriate pretreatment.

Landfill leachates are today often subjected to a process combination consisting of biological treatment, ultrafiltration, and activated- carbon adsorption [445]. In this case biological problems related to the activated carbon are largely avoided as a result of the ultrafiltration step.

Powdered carbon can be reactivated by wet oxidation. Granular and formed carbons are thermally reactivated in rotary or shelved kilns as well as in fluidized beds. This reactivation can be undertaken by either the user or the producer, with economic considerations normally dictating the choice.

5.1.7.2. Purification with Lignite Coke

In many cases, lignite coke is utilized instead of activated carbon for wastewater purification. Technical considerations play a role, but economic factors are most important. Lignite coke is certainly less expensive than activated carbon, but this is offset by lower adsorption efficiency. If relatively large amounts of lignite coke are to be employed it is necessary to take into account process-engineering considerations, logistics, and disposal technology.

5.1.7.3. Purification with Aluminum Oxide [435], [437], [446–450]

Treatment with activated aluminum oxide, especially γ-Al_2O_3, results in hydrophilic substances [446], [447] being sorbed at the solid surface, where they are retained by surface precipitation. This effect is exploited for the treatment of wastewaters from pulp production, above all from chlorine bleaching [446], [448].

Contaminated aluminum oxide was at one time regenerated thermally, but serious operational problems were encountered both in the adsorption filters and in the rotary kilns. Adsorptive wastewater purification of this type was largely abandoned after it became possible to improve the quality of wastewater by altering the corresponding production processes.

There has been some discussion of using α-Al_2O_3 for the elimination of fluoride, but especially of phosphate [449], [450]. Surface precipitation on the α-Al_2O_3 is then removed by extraction with sodium hydroxide solution, in the course of which residues can be recovered.

5.1.7.4. Treatment with Adsorber Resins [437], [451–462]

Adsorber resins are used in wastewater treatment for the targeted removal of both hydrophobic and hydrophilic organic compounds. This is possible since adsorption is in this case overshadowed by the formation of solid solutions in the adsorber matrix. In process-engineering terms the procedure can be described as adsorption and extraction with a solid solvent. It must always be borne in mind when using such adsorbers that they tend to swell in the course of taking up organic solutes.

Adsorber resins are normally regenerated by extraction with methanol, acetone, and other solvents. Appropriate processing of the extracts permits the solvents to be recovered and the eliminated organic materials to be isolated. Adsorber resins are therefore the adsorbents of choice for final purification of wastewater streams containing low concentrations of chlorohydrocarbons [455–457] and wastewater purification designed to facilitate recovery of the extractant and isolation of specific organic compounds [451–455].

5.1.7.5. Purification with Isopolyacids

The addition of iron(III) salt solutions, aluminum salt solutions, alkaline sodium aluminate solutions, or water glass to wastewater leads, depending on the pH, not to pure metal hydroxides, such as $Fe(OH)_3$ and $Al(OH)_3$, but rather to macromolecular hydroxides linked together via oxygen bridges. This can be illustrated as follows for formation of the first oxygen bridge:

$$2\,Fe^{3+} + 5\,OH^- \longrightarrow (OH)_2{-}Fe{-}O{-}Fe{-}(OH)_2 + H^+$$

If isopolyacids are used in a targeted way for wastewater purification, several elimination mechanisms can be in effect simultaneously:

1) Colloids may be destabilized and flocculated
2) Hydrophobic organic compounds may be bound adsorptively
3) Hydrophilic organic compounds may be precipitated or sorbed by ion exchange
4) Metal ions may be incorporated into the isopolyacid by coprecipitation

For this reason, metal salt solutions can be usefully incorporated prior to neutralization, concurrent with biological purification (for phosphate precipitation) and/or subsequent to biological purification.

The resulting contaminated isopolyacids must ultimately be separated from the wastewater and appropriately treated. Since they usually arise in conjunction with preclarification and excess sludge in central clarification plants, they are typically attended to as a part of clarification-sludge processing.

5.2. Mechanical Treatment

The goal of mechanical processing is to separate undissolved components from wastewater. The range of targets extends from debris and sand in the case of municipal sewage to coagulated sludge and oil emulsions in industrial wastewaters.

All the mechanical separation processes in current use can be related to one of two principles: *sieving* or *gravity*. Screens, sieves, and filters operate on the basis of sieving; sedimentation plants, floatation plants, flotation plants, foaming-out plants, and centrifugal plants are driven by gravity. Crucial to the choice of a particular process and to its effectiveness, aside from a difference in density between the components of interest and the wastewater matrix, is particle size.

5.2.1. Screening Processes [459–462]

A *bar screen* consists of parallel rods (usually made of steel) that are inserted in the wastewater channel in such a way as to intercept coarse and bulky materials (e.g., pieces of wood, fabric, boxes, etc.). The screens must then be cleaned, either manually or mechanically. Bar screens are used less for the removal of pollutants than as a way of protecting various downstream installations (e.g., pumping stations) from damage and blockage. The collected screenings are disposed of by consignment to a landfill or incineration. Figures 143 and 144 are schematic illustrations of such screens installed in wastewater channels, including provisions for both manual

and automatic cleaning. In the case of mechanical cleaning a distinction is made between *bar screens, curved bar screens*, and screens cleaned with *circulating rakes*. The gap between bars is generally 1 – 10 cm wide. Mechanical cleaning is initiated by a pressure differential and/or the elapse of a certain amount of time. Because of the risk of the screens icing in winter, and also because of the possibility that odors might develop, these facilities must be enclosed within a housing of some type. Screens can also be combined with *comminutors*, which crush the intercepted screenings in such a way that they can pass through the bars. This provision has the disadvantage that it increases the wastewater pollutant load, however, and comminutors do not always work satisfactorily with large amounts of textile residue or other long-fibered materials.

Sieving plants (Fig. 145) are applicable above all in the industrial field for the separation and potential recovery of fine solid particles. Sieve apertures are normally 0.1 – 5.0 mm. The construction material may be high-grade steel or plastic.

Belt sieves, drum sieves, and *disk sieves* are circulating or rotating devices. The corresponding sieving surface consists of fabric or of slotted or perforated metal sheets. After emerging from the water the separated solids are removed by rinsing or shaking. Continuous cleaning is necessary in order to minimize losses of efficiency due to blockage.

Belt sieves (Fig. 145 A) are especially well-suited to very large and highly variable flow rates. With most drum sieves (Fig. 145 B) the water runs from the interior outward through the rotating sieve drum. Material collected on the sieve is sprayed loose from the outside toward the center, where it falls into a collecting channel.

A curved sieve (Fig. 145 D) consists essentially of a feeding device and a concave surface, and it is self- cleaning in operation. Wedge-shaped profiled rods are arranged perpendicularly to the flow direction of the water. A relatively steady overflow ensures that the screen will clean itself. The various screen segments are all interchangeable. Typical gap widths are 0.02 – 2 mm for sieve areas of 0.1 – 3.0 m^2 [maximum throughput 300 $m^3/(m^2 \cdot h)$]. Curved screens are frequently used in preserve factories and slaughterhouses as well as in the paper and pulp industries.

Microstraining (Fig. 146) is used mainly for more complete elimination of suspended material in wastewater-treatment effluents. A rotating drum fitted internally with fine gauze (e.g., a high-quality alloy-steel gauze) serves in this case as the sieve. The mesh width is usually 5 – 100 µm, with peripheral speeds of ca. 50 m/min. The process stream runs from the inside of the rotating drum outward. About one-third of the drum projects above the water. In this region the gauze screen is continuously cleaned from the outside by water sprayed through nozzles (at ca. 3 bar). The water required for this purpose is equivalent to 2 – 5 % of the volume of the treated effluent. The hydraulic surface-loading of a microstrainer is 10 – 20 $m^3/(m^2 \cdot h)$. Micros-

training represents a borderline case that could also be classed with the filtration processes.

Figure 146. Schematic section through a microstrainer unit [462]
A) Cross-section; B) Longitudinal section

Figure 147. Mechanism of cake filtration [462]
a) Cake; b) Medium

In *filtration*, a fundamental distinction is made with respect to the filtration mechanism between *cake filtration* (Fig. 147) and *deep-bed filtration* (Fig. 148). With cake filtration, the uppermost layer of the filter cake operates as a sieve, so that even particles with diameters smaller than the pore size of the medium are also separable. In deep-bed filtration (e.g., a sand filter), separation takes place in the channels and pores of the filter bed itself.

Figure 148. Mechanism of deep-bed filtration [463]

In designing a filtration plant it is necessary to take into account the fact that during operation the pressure drop increases to a degree related to the extent of the solids retained. Once a filter becomes loaded the collected material must be released by backwashing. The resulting backwash water then usually becomes subject to treatment as well.

Very high levels of purity can be achieved by filtration, for which reason such processes are commonly used as a preliminary treatment for the removal of interfering suspended matter prior to other purification measures (adsorption, ion-exchange, etc.), or as a final purification step analogous to microstraining (e.g., for achieving established limits for suspended matter in the discharge from a biological treatment plant).

Deep-bed filtration entails less frequent backwashing than cake filtration, and thus a lower requirement for backwash water. For this reason, cake filtration is applicable only in exceptional cases in wastewater treatment.

Sand with a grain size between 0.5 and 3 mm is usually used as the filter material in the *sand*

filter version of deep-bed filtration (Fig. 149). The process stream usually passes downward through the filter at a surface-loading rate of $5-10\,m^3/(m^2 \cdot h)$. High solids concentrations lead to short filtering times and a heavy requirement for backwash water, so the solids concentration in the feed to a sand filter should not be allowed to exceed ca. 40 mg/L.

Figure 149. Design and operation of an open sand filter
A) Filtration; B) Backwash
a) Filter bed; b) Expanded filter bed

1 – 2 % of the filter effluent is used for the backwashing of a sand filter. Backwashing is conducted as soon as some predetermined pressure difference is exceeded, or at preselected time intervals. Backwashing can be expected to take 20 – 50 min, and is effectively accomplished by alternate introduction of air and water.

In the case of continuously working sand filters a distinction is made between *moving-bed filters* (Fig. 150) and *gravity filters* (Fig. 151). In a moving-bed filter the raw water runs from below, countercurrent to a sand bed that is sliding downward. In a gravity filter the backwashing process is initiated automatically by differential pressure via a water siphon. The amount of water required for backwashing a continuously working sand filter is about 5 % of the filtrate.

Filter presses operate with an overpressure of up to 15 bar, generated by piston diaphragm pumps that compress the suspension onto a system of filter plates (Fig. 152). These plates are covered with a stretched filter cloth and arranged in parallel array at a distance corresponding to the cake thickness. After compression is complete, the plates are pushed apart one after another, either mechanically or manually, permitting the cakes to fall out.

Figure 152. Schematic illustration of a filter press [463]
a) Filter cloth; b) Filter plates

Vacuum filters dehydrate a suspension with the aid of reduced pressure. Rotary-drum filters are frequently used for this purpose. The suspension is fed continuously into a trough in which the drum, covered with stretched permeable cloth, is about half submerged. Solids are sucked onto the cloth by reduced pressure, simultaneously removing water from the suspension. As the drum slowly rotates, the filter cake is doctored off the filter cloth by a removal device.

5.2.2. Gravity Processes [459], [460], [463–465]

The most important of the mechanical wastewater-treatment processes are gravity processes, especially sedimentation.

5.2.2.1. Sedimentation (→ Sedimentation)

Grit chambers (sand traps) are indispensible if a waste-treatment plant is also obliged to deal with rainwater, which normally entrains a considerable amount of sand. This might otherwise be deposited in many inconvenient places, and it could also lead to rapid abrasion in the pumps. Grit chambers in a wastewater-treatment plant are usefully situated immediately downstream from the screen that protects them from coarse and fibrous materials. Grit chambers are designed to handle a horizontal flow rate of ca. 30 cm/s. As a result, only sand is separated, whereas the lighter sludges are carried on further by the flowing liquid.

Three different types of grit chambers can be distinguished. The *channel-shaped horizontal-flow* grit chamber (Fig. 153) has a cross section of such a shape that a flow rate of 30 cm/s can be maintained in combination with a venturi flume located immediately downstream, even with variable wastewater streams. Alternatively, a similarly constant rate of flow can be achieved in a highly fluctuating wastewater stream by incorporating into the effluent region a baffle plate adapted to conform to the cross-section. With small fluctuations, a grit chamber with a parabolic or trapezoidal cross-section will suffice. Small grit chambers are cleaned manually, larger ones mechanically with the aid of scraper systems or air-jet lifts.

Figure 153. Channel-shaped horizontal-flow grit chamber with a venturi flume
a) Venturi flume; b) Drainage; c) Sand storage

Figure 154. Circular grit chamber
A) Cross-section; B) Top view
S = Sand

In the case of a *circular* grit chamber (Fig. 154), the water is introduced tangentially, causing the contents to circulate. As a result,

grains of sand are washed to the center where they can be removed with an air-jet lift. However, this type of grit chamber is less suitable for highly fluctuating flow rates.

In the *aerated* grit chamber (Fig. 155), circulation of the contents is achieved by an injection of air such that a flow rate of 30 cm/s results at the bottom. The bottom of the tank should be rounded in order to ensure undisturbed rotation. Aerated grit chambers can be combined effectively with a means for the separation of floating matter, and they also operate flawlessly with fluctuating flow rates.

Figure 155. Aerated grit chamber

Settling tanks (Fig. 42) are not usually used alone, but are rather integrated into a sequence of treatment steps, for example, as primary and secondary clarifiers in mechanobiological treatment facilities or as components of precipitation-flocculation-sedimentation plants.

Again, three main types of construction can be distinguished:

1) Rectangular tanks with horizontal flow (Fig. 42 A)
2) Circular tanks with horizontal flow (Fig. 42 B)
3) Hopper-bottom ("Dortmund") sedimentation tanks with vertical flow (Fig. 42 C)

In the circular and rectangular flat tanks the settled sludge is removed with such continuously working devices as suction dredges or sludge scrapers. Hopper-bottom sedimentation tanks usually have no provision for mechanical sludge removal. Oil, grease, and other floating materials are retained by inverted baffles set ahead of the tank outlet. An important consideration in the sizing of a settling tank is the settling rate of the suspended solids. Figure 156 shows settling tracks for (A) discrete and (B) flocculated particles in an ideal settling tank. The discrete particles settle at a constant rate, whereas flocculated particles settle at an ever-increasing rate, because the floc continuously grows as a result of flocculation and agglomeration phenomena. At high flocculated-sludge concentrations, such as those found in secondary clarifier tanks associated with activated-sludge plants, settling is impeded by mutual interaction of the sludge flocs. Properly designing a settling tank requires that experiments be conducted to establish the anticipated settling rate. Once the settling rate is known, the maximum permissible hydraulic surface loading of the proposed tank can be ascertained. The hydraulic surface loading, expressed in m/h, is the quotient obtained by dividing the flow rate of effluent water by the active surface area (clarification surface) of the sedimenter [$(m^3/h)/m^2 = m/h$]. In the case of nonflocculating particles the effectiveness of the treatment depends only on the surface area of the tank, not on the tank depth. With flocculating ingredients the depth of the settling tank becomes important as well, since the further the suspended solids settle the larger they become, and thus the faster they settle. Aside from the surface area, and therefore the hydraulic surface loading, other crucial parameters are the tank volume and the residence time. Table 17 gives an indication of maximum permissible hydraulic surface loadings. For use as a secondary clarifier tank in conjunction with an activated-sludge facility another parameter taken into account for sizing the tank surface area is the solids-surface loading. This is obtained by dividing the rate of biomass settlement in the secondary clarifier tank (in kg/h) by the tank surface area in m^2, and is thus expressed in units of $kg\,m^{-2}\,h^{-1}$. Satisfactory values generally fall below 3 kg of total suspended solids per square meter per hour.

Table 17. Hydraulic surface loading, in m/h; based on [464]

	Primary clarifier	Secondary clarifier	Intermediate clarifier
Mechanical treatment only	1.5 – 0.8		
With chemical precipitation	4 – 2.5	1.5 – 1.0	>2.5
With trickling-filter plant	1.5 – 0.8	1.5 – 1.0	>2
With an activated-sludge plant	4 – 2.5	1.2 – 0.5	>2.5

Figure 156. Settling tracks in an ideal settling tank for (A) a discrete particle and (B) a flocculated substance
a) Inlet zone; b) Sludge zone; c) Outlet zone

The principle underlying the *parallel-plate* (or *lamella*) *separator* (Fig. 157) is the fact that separation efficiency for a nonflocculating sludge is independent of the tank depth. The active clarification surface can be increased by installing inclined parallel plates in the separating chamber, thereby permitting the device as a whole to be smaller and more compact. The plates are set at an angle of inclination between 45° and 60°, with a plate spacing of a few centimeters. Owing to the small plate spacing, coarse contaminants can lead to blockage. Separation of biological sludge with the aid of plate separators is associated with certain risks, since the plates can also serve as growth surfaces for microorganisms. If such growth becomes too severe it may roughen the plates to such an extent that sliding of the sludge is impeded.

Figure 157. Parallel-plate (lamella) separator
a) Oil; b) Sludge

In practice, the separating efficiency of conventional settling tanks is often greater than that of parallel-plate separators, but the latter offer the advantage of reduced investment costs and above all a lower space requirement.

Parallel-plate separators are used both for the removal of settleable solids and for the removal of light, floating materials, such as oil in water, and especially for combining the two processes (see Fig. 157).

5.2.2.2. Floatation

Substances that are lighter than water, usually in suspended form, can be removed at the surface by floatation: in separating pits (Fig. 158 A), grease separators (consistent with DIN 4043; see Fig. 158 B), oil separators (DIN 4041), or gasoline separators (DIN 1999). The standards cited rely on the feed rate as a sizing criterion for the various separators. The separation effect is expected to be 95 % in each case. For a gasoline separator the sizing recommendations are based on a permissible surface loading of 18 $m^3/(m^2 \cdot h)$. Most separators described are available in ready-made form. Tipping troughs and overflow channels are usually used for removing collected residue.

Figure 158. Examples of flotation separators
A) Separating pit; B) Grease separator equipped with a sludge trap
a) Inverted buffles; b) Light materials; c) Sediment (sludge); d) Sludge trap; e) Grease separator

The parallel-plate type of separator has already been described in the preceding section (Fig. 157). On the underside of the inclined plates, separated oil droplets rise to the water surface, whereas material collecting on the upper sides slides off to the tank bottom.

5.2.2.3. Flotation (see also Section 3.1; → Flotation)

In the process known as flotation (not to be confused with flo*a*tation; "flotation" is an artificial type of floatation) suspended particles are *caused* to float by becoming attached to very fine gas bubbles. In this way suspended solids that would otherwise be difficult to separate because of a small density difference relative to the wastewater matrix are raised to the surface. Flotation is applicable to both small and large amounts of wastewater, especially for the recovery of oils and greases, but also for the pretreatment of wastewaters from slaughterhouses and paper and cellulose production. Flotation facilities are also sometimes used for sludge thickening, and for easing the burden on (or even replacing) secondary clarifier tanks in biological wastewater-treatment plants.

Depending on the technique used for bubble generation, a distinction is made between induced air flotation, electro-air flotation, and pressurized dissolved-air flotation (see Section 3.1.3). Wastewater technology takes advantage of pressurized dissolved-air flotation almost exclusively. A distinction is made in this context between full-flow treatment (Fig. 159), in which all of the wastewater influent is saturated with air at a certain pressure, and the circulation or recycling process (see Fig. 108), in which a portion of the treated water is isolated, saturated with air, and returned to the flotation vessel. The flotation effect can be enhanced by a preliminary flocculation.

Figure 159. Flotation system for full-flow treatment
a) Pressurizing pump; b) Pressure chamber; c) Reducing valve; d) Flotation tank; e) Sludge remover (skimmer)

Flotation tanks can be either rectangular or circular. They must be designed to permit a flow pattern in the flotation vessel that is as uniform as possible, with a minimum amount of turbulence. Apart from the hydraulic surface loading, the solid-surface loading and the air/solid ratio represent important design criteria. Optimum design values depend heavily on the nature of the suspended particles subject to treatment, and must be established with the aid of special test apparatus. The air/solid ratio must be between 10 and 30 g of air per kilogram of total suspended solids.

Figure 160. Foaming-out processes [462]
A) Aeration tank; B) Aeration tower
a) Foam; b) Water; c) Foam breaker; d) Foam remover (skimmer)

The flotate is usually removed from the surface mechanically, and some type of discharge provision is also usually required for solids that sediment in the flotation system.

Compared with sedimentation separators, flotation devices are characterized by low structural volumes but high operating costs attributable to energy expenditures.

5.2.2.4. Foaming-Out Process

Foaming-out (Fig. 160) is a way of removing various foam-forming substances (e.g., surfactants and saponins), which because of their surface-active character tend to accumulate at the water – air interface. Two modes of operation can be distinguished. With systems based on an *aeration tank* (Fig. 160 A), foam is swept out with a belt foam remover and destroyed in a foam breaker; if an *aeration tower* is employed instead (Fig. 160 B), foam reaches the foam breaker without assistance.

5.2.2.5. Centrifugal Processes

Centrifugation is a way of increasing dramatically the effect of gravity on suspended substances. As a result, even suspended solids that are incapable of settling under normal conditions can be induced to separate.

Decanting centrifuges (also known as decanters), *filtering centrifuges*, and *separators* all find application in wastewater technology. With a decanting centrifuge (Fig. 161) thickened solid is discharged continuously from the interior of the centrifuge by means of a screw. The filtering centrifuge relies on centrifugal force to enhance the filtering effect. Separators are able effectively to isolate both suspensions and other materials with densities differing from that of the matrix medium. Centrifuges are most often employed in sludge treatment, especially in the form of decanters for sludge dewatering.

Figure 161. Decanting centrifuge (base omitted) [465]
a) Differential-speed gearbox; b) Rotating bowl; c) Rotating conveyor; d) Cover; e) Main drive shaft; f) Bearing

Hydrocyclones (→ Hydrocyclones) could also be classified as centrifugal separators, and these are called upon for such purposes as desanding, classification and thickening of industrial slurries and sludges, and the separation of granular suspensions. In the case of a hydrocyclone, the suspension subject to treatment is fed into the device tangentially, as a result of which the mass of liquid is induced to circulate and solids are flung onto the wall, where they migrate downward. Hydrocyclones are adapted to suit the size of the particles to be separated: small particles demand higher operating pressures and smaller cyclone diameters. Hydrocyclones for wastewater-treatment applications should have a diameter of at least 300 mm to minimize the risk of clogging. The separating efficiency of a hydrocyclone is strongly affected by fluctuations in the feed rate.

6. Wastewater Incineration

6.1. Introduction

Wastewaters for which biological, chemical, and physical purification processes either fail or prove too expensive can, if necessary, be purified by combustion of their organic constituents. In principle, all organic substances can be oxidized in a flame, and volatile inorganic substances formed can be separated in a flue-gas scrubber. Oxidation in a flame and the associated breakdown of organic materials depends on temperature, residence time, oxygen content, and turbulence in the combustion chambers.

The incineration of organic constituents is a specialized process for treating those industrial wastewaters in which the organic constituents, and under some circumstances the inorganic constituents as well, are chemically oxidizable at high temperature with the aid of atmospheric oxygen; the accompanying water matrix is simultaneously vaporized. The expression "gas-phase oxidation" [466] is also used in conjunction with this type of combustion to distinguish it from processes such as wet oxidation (see Section 4.4).

In the course of this treatment organic materials are converted almost completely into inorganic reaction products, mainly carbon dioxide and water, together, in some cases, with nitrogen oxides, sulfur oxides, or halogen compounds. During the incineration process such inorganic

constituents of the wastewater as salts lead (depending on the temperature and the formation of eutectic mixtures) to slags, ashes, or ash sludges, which can either be reused or (depending on the nature of the flue-gas treatment) be diverted for collection or disposed of as waste. Dust and gaseous substances foreign to air that may be present in the flue gases include heavy-metal compounds, sulfur dioxide, hydrogen halides, and phosphates, and these must be removed by appropriate means.

The process of gas-phase oxidation is particularly suitable [467], [468] if:

1) Organic constituents in the water cannot be reused, or their processing is unprofitable
2) The contaminants constitute a multicomponent mixture in which both the concentration of the mixture and the mixing ratio of the components vary continuously
3) Apart from organic materials the wastewater also contains considerable amounts of inorganic matter
4) The materials present are poorly biodegradable or biologically toxic
5) Contaminant levels, time demands, and economic considerations justify the erection of such a plant
6) The salt content is so high that the wastewater in question is treatable biologically only after considerable dilution
7) Incineration would make it possible to produce valuable products, or to recycle feed materials – salts, for example

Many other processes compete with gas-phase oxidation, including adsorption (Chap. 5), stripping, low- or high-pressure wet oxidation (Section 4.4), reverse osmosis, etc. The choice of a particular method usually depends on the environmental situation at the treatment site together with investment and operating costs [469].

Wastewater incineration is an exothermic process. Nevertheless, an incineration that is self-sustaining from an energy standpoint is achievable only if the organic load is sufficient to ensure adequate support for vaporization and superheating of the water present [469], [470]. If the organic burden is low, a wastewater incineration plant must therefore be operated with a supporting flame [471], [472]. The requirement for additional energy can be reduced by lowering the water content of the feed. This can be accomplished, for example, with a single- or multistage evaporation unit situated upstream. Installation of a heat-recovery section (boiler) may be a convenient way of generating steam from the resulting heat of combustion, steam that might in turn be used for evaporation purposes (Fig. 162) [466].

Wastewater incineration is highly demanding with respect to both technology and energy. In the development of a suitable furnace chamber, for example, account must be taken of the chemical effects of the wastewater subject to thermal treatment in terms of corrosion behavior, the technology envisioned, and possibly the refractory lining.

Thus, depending on the nature of the individual organic and inorganic constituents in the wastewater and relevant local factors, very different plant designs might result, and each plant must generally be tailored to a specific situation.

6.2. Legal Aspects [473]

Construction of a wastewater- combustion facility requires compliance with all applicable laws and statutes. In the Federal Republic of Germany, for example, such facilities must be in conformance with provincial wastewater law (Landesabwasserrecht). In the event that combustion of liquid or solid wastes other than wastewater is contemplated it is necessary to acquire permission under the German Federal Pollution Control Act (17th BImSchV, regulating combustion facilities for wastes and similar combustible materials).

The costs of wastewater combustion are subject to dramatic increases as a result of the need to meet specified emission limits and lowest acceptable temperatures, and in some cases because of administrative expenses. Similarly, account must be taken of the inevitable time lapse between the filing of an application and the granting of a permit.

6.3. Distinctions with Respect to Other Processes, and Evaluation Criteria

Organic constituents are destroyed during the incineration of wastewater, so it is always important to investigate the alternative possibility

Figure 162. Schematic view of a typical wastewater-incineration (gas-phase oxidation) plant with flue-gas washing
a) Wastewater storage tanks; b) Combustion chamber; c) Process-gas cooler; d) Molten salt; e) Discharged salts; f) Quenching system; g) Jet washer; h) Electrical precipitator; i) Fan; j) Stack

of recovery by such processes as adsorption, ion exchange, distillation, evaporation, stripping, extraction, reverse osmosis, or crystallization, which in some cases may even offer significant advantages [474], [475].

Important criteria related to wastewater incineration and for selection of the type of facility to be constructed or the recovery process to be instituted for heat and/or valuable substances include:

1) The calorific value (heat equivalent) of the wastewater, which is an essential quantity for assessing the supplementary firing (fuel) requirement. A self-sustaining combustion can be anticipated with a calorific value of ca. 6000 – 12 000 kJ/kg.
2) The nature, amount, and variability of the wastewater and its organic and especially inorganic constituents. This strongly influences such factors as the preferred type of furnace, the construction materials to be used, the potential for heat utilization, and flue-gas treatment.
3) Legal aspects, including probable requirements under licensing law, the role of location, and possible consequences under tax law.

6.3.1. Calorific Value

The first consideration in terms of thermal disposal of wastewater should be the calorific value, because it is upon this that fuel consumption and therefore overall operating costs will depend. For example, if the calorific value of a wastewater is zero, then for 1 t of wastewater at a combustion- chamber temperature of 1000 °C and with a 40 % excess of air at 6 % residual O_2 and 5 % radiation loss, ca. 250 kg of light fuel oil would be consumed for evaporation and superheating. If the air is somehow preheated from 20 °C to 300 °C this estimate can be lowered to just under 200 kg of fuel oil. With heat recovery by steam generation (exit-gas temperature 300 °C), the fuel-oil requirement can be reduced substantially, to 91 – 100 kg per ton of water. For easily combusted constituents, complete burn-out can be achieved even at low temperatures and with little excess air or residual O_2. The advantages, apart from an energy saving, are less NO_x formation as well as a correspondingly smaller facility [469], [474], [476].

For wastewaters with low calorific values it is advisable to install multistream burners, introducing light fuel oil or waste solvent separately from the water via flame-vaporization burners.

Destroying the organic constituents quantitatively requires that optimum distribution be assured in the furnace chamber. This is achieved by the addition of an atomizing medium, such as steam or compressed air (2 – 15 bar). The viscosity of the wastewater must also be taken into account in the process, along with such parameters as particle size and particle-size distribution.

6.3.2. Wastewater Constituents

During the course of incineration, specific wastewater constituents can create various problems both in terms of the combustion process itself and in subsequent flue-gas treatment, thereby influencing the choice of the incineration facility and the associated treatment equipment [477]. Volatile organic materials in dissolved form and devoid of heteroatoms other than oxygen are unproblematic. Their combustion leads to virtually no ash, dust, or troublesome emissions. Vapor-phase feed is possible, and there is no problem with heat recovery. The same is true of dissolved, suspended, or emulsified organic matter (e.g., carbohydrates, fats or greases, lignosulfonic acids, condensates, and polymers). Emission problems arise only with halogen- or sulfur- containing materials. Vapor-phase introduction is in this case not possible, however.

In the incineration of wastewaters containing inorganic salts, and sometimes also with mineral acids or alkalis, one must be prepared to deal with aerosols and dusts that are difficult to remove. Special separators are required, and heat recovery in the form of steam is technically more difficult. In addition, damage can be expected with respect to ceramic materials (refractory lining) from alkalis and salts, especially phosphates and carbonates. Any melts, ashes, or dusts formed must be removed and discarded. Aside from emission problems and the presence of dust and ash, there is also a risk of incrustations and blockages in the combustion- chamber inlet and in the waste-heat boiler from salts or oxides of calcium, magnesium, and iron. Acids present the further challenge of metal corrosion.

6.4. Incineration Plants

The design of an incineration plant is influenced primarily by the nature of the wastewater subject to disposition. In this connection the most important factors are quantity, calorific value, salt and solid content, and the content of such heteroatoms as sulfur, nitrogen, the halogens, and phosphorus in the organic materials present, not to mention excessive amounts of acidic or alkaline constituents. The processes envisaged for treatment, removal or recovery, and possibly steam production also play a role, as do legal requirements that must be met.

In the case of strict wastewater incineration the choice will probably be between a simple or a cooled combustion chamber and a fluidized-bed furnace, whereas for combined incineration with solid wastes a facility such as a rotary kiln may be an option. Co- combustion in a boiler for steam generation is also a possibility in special cases [478], although rather severe restrictions may apply as a result of the salt content and its melting or softening point.

It is always important to ascertain whether a preliminary evaporation prior to incineration might be less expensive than direct incineration of the wastewater itself [472]. Even if the vapors still must be combusted it can be advantageous to concentrate the wastewater with the aid of waste heat obtained from the actual combustion process.

With wastewaters containing low concentrations of contaminants it may be possible to reduce the specific steam consumption from 1 kg of steam per kilogram of water to ca. 0.2 kg of steam per kilogram of water by a five-stage evaporation. In order that the flexibility of the incineration not be too seriously restricted by preliminary evaporation, an intermediate tank should be installed between the corresponding facilities.

6.4.1. Combustion Chambers

When incinerating a wastewater stream, perhaps in conjunction with waste solvents or waste air, a combustion chamber fixed in a horizontal, inclined, or vertical position is most appropriate depending on the salt and solids content [479], [480]. This is especially the case at relatively high incineration temperatures (>900 °C, "high-temperature combustion"). Compared with a facility designed for lower temperatures, such as a fluidized-bed furnace, a combustion chamber of this type offers greater flexibility with respect to fluctuations in throughput and wastewater composition.

A vertical mounting has been found to be particularly advantageous if salts must be removed in molten form at the bottom of the combustion chamber [466], [481], [482]. A horizontal arrangement with a downstream waste-heat system is preferable if salt removal is not required.

Inclined combustion chambers have also been used.

Wastewater and fuel are charged via burners or special nozzles, sometimes at several points within the combustion chamber. Air – both "primary" or combustion air added jointly with the fuel, and "secondary" or mixing air supplied, for example, via an annular conduit – is likewise introduced at several points, usually with a spinning impulse. The temperatures in the individual combustion zones can be regulated via the supply of fuel or air. Thus, if the combustion chamber is large enough it is possible to conduct a deliberate two-stage combustion (e.g., wastewater in a first stage, and waste gas in a second stage, each with different residence times and temperatures. The combustion chamber must be of such dimensions that the residence time of the flue gases is sufficient for complete combustion. Allowance must also be made for a sufficient excess of air).

A combustion-chamber temperature of at least 800 °C is generally necessary for the complete incineration of wastewater constituents. An increase in the combustion temperature not only raises the costs (energy consumption, maintenance) but also the proportion of nitrogen oxides in the flue gas, so the temperature should not be higher than absolutely necessary. However, it is important to ensure that all organic constituents are oxidized almost completely. In some cases it is possible to take advantage of special design features or air-supply techniques (e.g., "recycle burners", a stepwise mode of operation in the combustion chamber) as a way of suppressing the formation of nitrogen oxides [471], [483], [484].

Formation of such acidic flue-gas constituents as SO_2, HCl, and HF can be prevented by ensuring sufficient alkalinity in the wastewater, a precaution that can also greatly simplify and reduce the cost of subsequent flue-gas purification [466].

If substances other than "typical fuels" are also used as energy carriers in such plants, higher incineration temperatures (e.g., 1200 °C) and longer residence times may be stipulated (e.g., 17th BImSchV).

The casing of a combustion chamber is usually made of steel, and frequently equipped with a refractory lining. The lining is subject to attack if alkali-metal carbonates or other alkaline substances are formed during the combustion process. For this reason a hard skin of slag should, if possible, be maintained on unlined portions of the wall (by ensuring that there is a temperature gradient toward the outside), over which the melt can flow. A refractory lining is less sensitive to acidic constituents, so no problems are likely to arise if acidic wastewaters are injected and incinerated. Nevertheless, a lining may be subject to attack by such acidic flue-gas constituents as hydrogen fluoride and phosporus pentoxide, as well as by saline vapors and saline melts. Appropriate preventive measures should be taken in the form of a suitable choice of materials and operating procedures. Damage to internal linings tends to be less with designs that incorporate cooling of the combustion- chamber wall, heat-transfer oils, or steam generation [466], [481].

If steam generation is envisaged then a proper choice of pressure and temperature is important with respect to low- and high-temperature corrosion attributable to chloride. Depending on the chloride content, corrosion can be kept, for example, to 0.1 mm/a by operating at 15 –30 bar, whereas at 6 bar and < 150 °C a corrosion rate of 1 mm/a must be anticipated. Above 300 °C there is a risk of stress corrosion.

Figure 163. Schematic view of an immersion heating chamber
a) Burner and combustion chamber; b) Immersion tube; c) Exit slits

With relatively large amounts of wastewater, heavy-duty combustion chambers characterized by high turbulence are recommended, where the air and wastewater are likely to be charged tangentially into the combustion chamber [485], [486]. Especially high throughputs can be achieved with flame-vaporization burners developed specifically for wastewater incineration [487].

In case of a high salt content, some portion of the salts (depending on the precise salt composition and the mode of operation) can almost certainly be withdrawn in the form of a melt at the bottom (exit) of the first chamber, but a large fraction of the salt usually leaves the combustion chamber along with the flue gases, and must subsequently be separated in filters and/or quenchers or flue-gas scrubbers. The salt content of the flue gas can however be reduced, for example, with filtering devices or quenchers.

6.4.2. Immersion Heating Chambers

A different type of thermal wastewater disposal is possible with what is known as an *immersion burner* [485], [488]. An immersion heating chamber is a vertical combustion chamber the lower part of which is immersed in a water bath (Fig. 163). It is here that the flue gases are quenched and precleaned.

For exclusively volatile organic wastewater constituents, situations sometimes arise in which the prior stripping of these particular substances is advantageous (e.g., via an immersion burner), with subsequent normal or catalytic combustion of the vapors. In this case evaporation of the aqueous portion can largely be omitted [489].

6.4.3. Fluidized-Bed Furnaces

Wastewater, especially in concentrated form, just like sludge or other solids-rich material, can be incinerated directly, either alone or together with other substances (Fig. 164) [486], [490]. However, such incineration in a fluidized-bed furnace is usually conducted only as a low-temperature process at 700 – 900 °C. The wastewater is fed into the furnace from above, or from the side. Preheated air is blown in from below. A supplementary firing is usually useful or even necessary. The water fraction is rapidly vaporized in the fluidized bed by intensive exchange of heat and material, and the organic material is oxidized.

Figure 164. Example of a fluidized-bed furnace [486]

The fluidized bed may consist of an inert heat-transfer agent such as sand, or of incombustible inorganic constituents from the wastewater itself. The latter is a feasible alternative only if the wastewater has a uniform composition, since a consistent supplementation of the fluidized bed is essential.

The fluidized bed must be kept at a temperature such that the solid constituents do not melt. Saline components of the wastewater such as sodium chloride, sodium carbonate, sodium sulfate, etc. (all of which have low melting points in pure or eutectic form) may thus lead to problems.

In the ideal case, inorganic constituents remaining after vaporization of the water and oxidation of organic matter will agglomerate, facilitating their removal in pellet form. A temperature $< 800\,°C$ for the fluidized bed and the salt discharge is usually necessary to ensure that the process will function smoothly, but this means that not all organic substances will be completely combusted, placing restrictions on the applicability of the process. Should a combustion temperature of 900 – 1200 °C be formally required (e.g., by law) then the energy savings of ca.

Figure 165. Example of a rotary-kiln system with flue-gas washing

2500 kJ per kilogram of wastewater associated with low-temperature combustion must be sacrificed [474].

Fluidized-bed furnaces play a significant role especially in the combustion of pulp-digester lyes, including chemical recovery. Because of the uniform and high content of inorganic constituents in this case, all the prerequisites for fluidized-bed processing are met, and plants of this type with throughputs of 10 – 30 t/h have operated satisfactorily for years in Germany and elsewhere. Taken on balance, however, the fluidized-bed process is less flexible than combustion in a combustion chamber.

6.4.4. Rotary Kilns

Rotary kilns are cylindrical, rotating steel furnaces, usually with refractory linings. They are arranged approximately horizontally, with a slight downward inclination (e.g., ca. 3°) toward the exit end. The material to be incinerated is usually charged at the front end (see Fig. 165).

Rotary kiln facilities are more expensive than fixed combustion chambers, but also more versatile in their applications, so that in addition to solid or viscous wastes (including containers), waste solvents, other liquid residues, and solvent- containing or odoriferous air can be incinerated as well [491]. Moreover, in special cases even wastewaters can be injected directly into such a furnace or the post combustion chamber.

Given such a wide variety of potential feeds and the corresponding variations in pH, combustion temperature, and other parameters, increased attentiveness and operating experience are necessary to ensure an adequate life time for the furnace lining. An attempt is made to keep corrosion and erosion within reasonable limits by selecting the highest-quality ceramic-lining material available (stability to 1400 °C, in some cases 1700 °C) and always ensuring the presence of a protective skin of molten slag. Despite these precautions, the lining of the rotatory kiln often must be renewed once or twice annually, with a shutdown each time lasting ca. 3 – 4 weeks.

6.5. Emissions: Off-Gases, Water, and Solid Waste

Requirements for flue-gas cleaning are set in Germany by the 17th BImSchV (see Section 6.2). This prescribes a limiting value for polychlorinated dibenzodioxins and -furans of 0.1 mg/m^3 of total emissions (at 0 °C, 1.013 bar), a value that is usually met by such special gas-phase oxidation plants. It is particularly important that the requirements regarding the parameters "dust" (particles) and "NO_x" be strictly observed.

Wastewater. Depending on the nature of the outlet or discharge, wastewater from a combustion plant in Germany is subject to either the

22nd or the 47th VwV (Administrative Regulation). Plants currently in the design phase should also be considered in the light of EC regulations.

Solid Waste. Solid residues from a combustion plant are frequently soluble salts, which cannot simply be discarded in above-ground disposal sites. In the case of a single stream of wastewater, reuse should certainly be considered, and it may even prove economically justifiable. With mixed salts, underground disposal remains the only practical solution.

1. Introduction

“Raw materials” is the name given to those materials whose constituents – after physical or chemical treatment – can be utilized by humans as a whole or in part, or whose stored binding energy can be released in the form of thermal energy.

Naturally occurring materials (e.g., ore, rock, or fossil material) are known as *primary raw materials*. Those materials that have already been in use or subjected to a physicochemical process, but whose constituents can be recovered and consequently returned to the material cycle, are termed *secondary raw materials*. Examples

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.b08_153

of these are scrap materials, metallurgical dust and slag, waste glass, and wastepaper.

Renewable resources are raw materials of vegetable or animal origin whose availability can be secured by fresh planting or breeding.

The need for raw materials results from the volume of all commodities and consumer goods that must be produced and from the amount of energy that must be used in the extraction of raw materials, the production of intermediate and end products, and the use of goods during their service life. From this, the important factors affecting raw material consumption derive directly: (1) population density or growth, and (2) standard of living or degree of industrialization.

The extraction of natural raw materials and the production and use of consumer goods are basically associated with effects on the natural environment. The effects can be described in a simplified way as follows:

*Extraction of Raw Materials*Impact on the countryside and frequently on the water resources of a region, disturbance of natural biotopes, consumption of energy
*Processing of Raw Materials*Production of emissions in air and water, formation of unusable residues, consumption of chemical and physical energy
*Manufacture of Consumer Goods*Production of emissions, formation of further residues, consumption of energy
*Use of the Goods*Consumption of further materials and energy, creation of waste at the end of the service life, and consumption of disposal site volume

Against the background of a steadily increasing world population and the rise of industrialization and of living standards in the newly industrialized and developing countries, effects on the environment caused by the totality of human activities and questions about the nature and availability of raw materials are becoming increasingly important.

2. Mineral Raw Materials

Mineral is a collective name for all elements and their compounds, mainly inorganic and rarely organic in nature, that occur naturally as constituents of the earth's crust. Solidified minerals, as an aggregate, form the rocks of the earth's crust; 99.4 % of the earth's crust is composed of compounds of only 11 of the 92 natural elements:

SiO_2	59.12 %
Al_2O_3	15.34 %
CaO	5.08 %
Na_2O	3.84 %
FeO	3.81 %
Fe_2O_3	3.08 %
MgO	3.49 %
K_2O	3.13 %
H_2O	1.15 %
TiO_2	1.05 %
P_2O_5	0.30 %

The distribution of chemical elements in the earth's crust is not homogeneous. Dynamic geological changes led to element regroupings (i.e., enrichment and depletion). If a regional element enrichment reaches a mineable concentration, this is called a deposit. Deposits form the natural basis of the raw materials industry.

2.1. Formation of Deposits

The most important deposits are the magmatic deposits. When the magma cooled down slowly, dark, low-quartz or quartz-free rocks were formed in this *early crystallization phase*. These rocks are based mainly on magnesium – iron silicates. Simultaneously, metals such as Cr, Pt, V, Ni, and Cu separated from the liquid magmatic phase and accumulated in the magma chambers (e.g., Ni – Cu – Pt deposits in Sudbury, Canada; → Platinum Group Metals and Compounds, Chap. 3.3.). The subsequent *main crystallization phase* of the magma led to the formation of quartz-bearing eruptive rocks, such as granite. Further cooling and the *late crystallization* occurring at the same time resulted in superheated aqueous solutions (hydrothermal springs), which absorbed a number of the metals important today such as Pb, Zn, Cu, Mo, U, Bi, Hg, Ag, and Au, as well as Ta, Zr, and Nb. Because of temperature and pressure gradients, the solutions diffused into the cavities, veins, and clefts formed during the consolidation stage. Because of appropriate physical and chemical conditions, the metals separated in the form of mixed crystals (e.g., the aurifer-

rous veins of Idaho Springs, United States or the zinc – lead deposits in Trepca, Serbia; → Lead). If, as a result of volcanic processes, hydrothermal springs emerged on the sea bottom, the dissolved metals were precipitated and formed volcanogenic – sedimentary deposits (Zn – Pb – Cu deposits in Kidd Creek, Canada or Pb – Zn deposits in Mount Isa, Australia). If metal-bearing rocks were brought up to the surface by emergence of land and therefore into the weathering zone, they were eroded as a result of physical or chemical processes and redistributed. In this way the so-called sedimentary deposits, in some cases with considerable enrichment, were formed (e.g., the copper belt of Zambia – Zaire; → Copper, Chap. 4.2.; gold placers in South Africa).

Through the settling of rock formations to greater depths, partial melting and new enrichment occurred, and *metamorphic* deposits were formed (e.g., the Zn – Pb deposits in Sulitjelma, Norway or Broken Hill, Australia).

Table 1. Mineral raw materials from the viewpoint of the raw materials industry

Raw material group	Examples
1. Ores	
1.1 Iron ores	hematite, magnetite, pyrite, goethite, siderite
1.2 Nonferrous ores	lead glance, zinc blende, copper pyrite, bauxite, cassiterite
1.3 Ores of alloying metals	molybdenum glance, chromite, vanadinite, cobalt glance, wolframite, rutile
2. Noble metals	metallic gold, platinum metals
3. Natural rocks	
3.1 Magmatic rocks	granite, basalt, pumice
3.2 Sedimentary rocks	limestone, sandstone, tufa
3.3 Metamorphic rocks	marble, slate, serpentine
4. Salt rocks	rock salt, sylvine, Glauber's salt
5. Quartz minerals	quartz, chalcedony, kieselguhr, flint
6. Clay minerals	kaolin, montmorillonite, illite, chlorite
7. Precious and decorative stones	beryl, jade, opal, topaz, turquoise, garnet
8. Rare earths, reactor fuels	monazite, cerite, thorite, pitchblende
9. Other minerals	
Nitrogen minerals	Chile saltpeter, saltpeter
Phosphate minerals, boron minerals	apatite, phosphorite, borax, colemanite

2.2. Mineralogy and Raw Material Groups

In *systematic mineralogy* the minerals are classified by the criteria of chemical composition and crystal structure into nine main groups:

Class I	elements
Class II	sulfides, compounds of As, Sb, Br, Se, and Te
Class III	halide salts
Class IV	oxides, hydroxides
Class V	nitrates, borates, carbonates
Class VI	sulfates, chromates, molybdates, tungstates
Class VII	phosphates, arsenates, vanadates
Class VIII	silicates
Class IX	organic compounds

From the viewpoint of the raw materials industry a grouping such as that shown in Table 1 is appropriate.

2.3. Development of Deposits

Deposit research is concerned with ascertaining the formation of individual deposits and presenting the results in the form of geoscientific (metallogenetic) models. Such a metallogenetic model, for example, led to the discovery of porphyry copper ores on the West Coast of North and South America, in the Southeast Asian island arc, and in the Balkans. About 50 % of present-day copper production originates from such deposits.

The *prospecting and development* of raw material deposits is divided into three main stages.

The first stage, *prospecting*, seeks to determine geological structures with potential enrichments in a relatively large target area, and possibly broadly to delimit these structures. During the second stage, *exploration*, the area in which recoverable deposits are suspected is explored in more detail with regard to the concentration, extent, and character of the mineral body. The following phase is the *exploitation* of the deposit. In this, the type of ore or mineral is more closely identified and the content of the entire mineral body calculated. Noteworthy effects on the environment do not appear up to the development of the deposit, if the negligible effects of trial borings are disregarded. This can change, however, drastically when *mining* begins. In many countries, therefore, extensive environmental compatibility tests must be carried out before a min-

ing permit is granted. In a feasibility study, the deposit is evaluated with regard to both technical and economic aspects. This means that the mineral must be minable by the application of available technologies, the necessary energy supply must be guaranteed, and transportation problems must be solved. The value of the ore body must cover the cost of exploration, mining, treatment, and marketing, as well as amortization of the investment within an acceptable period of time. If the profitability study leads to positive conclusions, the deposit is opened up. The time between exploration and opening is between five and ten years. The investment can be as much as $\$2\times10^9$ under difficult conditions, such as extreme climatic conditions, a lack of infrastructure, and long transportation routes [e.g., in the case of the copper – gold deposit of Ok Tedi (Papua New Guinea)]. Such projects can be handled only by financially strong international consortia.

2.4. Exploitation of Raw Materials

Depending on the structure and position of the mineral body, mining is carried out either two-dimensionally above ground (e.g., in the case of the saltpeter deposits in Atacama, Chile) or in the form of the technically simple and also very economical open-pit mining (e.g., the gigantic iron ore deposits in Minas Gerais, Brazil or Hamersley Range, Australia). In many cases, the position and structure of the ore body require technically complex underground mining.

With the exception of natural rocks such as granite, basalt, limestone, and marble, and of salt minerals such as rock salt, saltpeter, or sylvine, the substance of value in the extracted ore can be assumed to have too low a concentration to make direct metallurgical processing economically possible. In the case of low-content ores – particularly mixed ores with complex interstratification – expensive physicochemical methods are used: crushing, classification, pulverizing, flotation, or the sink-float process. In this way, not only can the gangue be removed, but concentrates of specific metals can also be produced. With decreasing metal content, however, the energy requirements rise exponentially; in many cases, therefore, the availability and price of energy determine the feasibility of a deposit.

The disposal of worthless rock, the creation of cavities or gigantic pits aboveground, the pumping away of mine water and, associated with it, the lowering of groundwater level – aside from intrusion into the landscape and disturbance of natural biotopes – represent the main environmental impacts from the mining of mineral law materials.

The ecological effect profile can therefore be classified as follows:

1) Interference with the natural water distribution in an area and, resulting from this, microclimatic change for plants and ground animals
2) Formation of emissions by deflation of heaps and dumps and from the operation of mechanical processing plants
3) Creation of wastewater through drainage of mine water and operation of flotation plants
4) Formation of residues as a result of overburden and separated gangue
5) Alteration of the natural appearance of the landscape (especially by open-pit mining)

With the exception of emissions into air and water, the remaining effects generally remain regionally limited and can be minimized by appropriate measures.

The depression funnel formed by pumping off mine water is generally many times the actual area of mining. Formation of the depression funnel can be partially compensated by extensive seepage of the water, instead of pumping it off. In many cases, previous treatment of the mine water is necessary. Iron and manganese, for example, must be removed, and in the case of nonferrous deposits, heavy metals (lead, copper, zinc, etc.), and possibly anions such as sulfide and sulfate, must be removed as well.

In open-pit mining, ca. 16×10^9 t of rock is produced per year worldwide, of which about 10×10^9 t is disposed as waste. By refilling, usually after having been stored in bulk for three to eight years, the greater part of a mined area can be recultivated. A mass deficiency remains, however, which can either be covered by filling with other, suitable residues or remain in the form of artificial lakes.

The ground surface must be protected from extensive subsidence, especially in underground mining. Subsidence occurs either through sagging of the overburden rock into the cavities

formed by mining or by extensive change of the flows of groundwater and associated subrosive effects (i.e., dissolution of rocks or rock constituents). The effects can be largely limited by a controlled water-distribution system and refilling the galleries and shafts.

2.5. Availability of Mineral Raw Materials

The question of availability and resources arises primarily with reference to the most important commodity metals such as iron, aluminum, copper, zinc, chromium, or nickel.

Salt minerals such as halides, phosphates, nitrates, and sulfates, apart from their recovery by the mining of natural raw materials, can be produced without difficulty by appropriate processes or are obtained to a certain extent as byproducts (e.g., desulfurization gypsum or ammonium sulfate during flue-gas scrubbing).

In structural and civil engineering, *natural rocks* such as granite, basalt, sandstone, and marble have been replaced to a large extent by concrete and steel and are currently used mainly for decorative purposes. Natural rocks based on quartz, clay, and feldspar minerals represent by far the predominant constituent of the earth's crust, and their availability is practically unlimited.

Geochemistry shows that most *metals* occur in the earth's crust with a statistically normal distribution, if the concentration is plotted logarithmically against the quantity, as shown in simplified form in Figure 1. According to this, most metals occur in concentration ranges that are not recoverable under present conditions because of high costs. According to McKelvey, by taking into account the actual basic technical and economic conditions, deposit reserves are classified with a constant confidence level of 90 % as follows [7]:

Extent and content of the ore body are known with a limit of error of
≈10 %: proven reserves
≈20 %: probable reserves
≈30 %: possible reserves I
≈50 %: possible reserves II

Figure 1. Distribution of metals in the earth's crust

The boundary lines drawn in Figure 2 (according to McKelvey) are not to be regarded as definite. More accurate exploration methods widen the field of known reserves; further development of mining methods and preparation processes, energy costs, and raw materials prices influence the boundary line between economic and subeconomic fields. The terms reserves and resources are thus dynamic quantities that are influenced by technoeconomic factors.

Given the reserves known today and the resources presumed with high probability, the possibility of replacing metals with plastics or ceramics, and advancing technical development, the supply of metallic raw materials is ensured for the foreseeable future.

2.6. Environmental Factors in the Processing of Raw Materials

The type of raw material, its recovery method, questions of location, the treatment process, the provision of environmental protection equipment, and other items naturally have a considerable effect on the environment. Table 2 shows the important environmental factors associated with aluminum, for example [8]. The effects of the mining and transportation of bauxite are not considered here. For comparison with the recovery of primary aluminum, the corresponding val-

Figure 2. Classification of mineral resources (according to McKelvey)

ues for secondary aluminum production are also given.

Table 2. Factors with environmental impacts in the production of primary and secondary aluminum

Factor	Primary aluminum	Secondary aluminum
Energy Consumption, MJ/t Al		
Alumina production	27 683	
Scrap preparation		1 752
Melting down, preparation of dross, sweepings, etc.		10 060
Salt slag preparation		3 376
Fused-melt electrolysis	129 618	
Refining	4 473	
Casting	1 956	2 016
Total	163 730	17 204
Residues, kg/t Al		
Red mud	3 175

Emissions, kg/t Al		
From primary energy generation	173	
Process specific	31	6
From melt energy consumption		6
Total	204	12

Supplying mineral raw materials to the treatment sites concerned and marketing the products are unavoidably combined with transportation processes. Table 3 lists the environmentally relevant factors of various means of transportation based on a study by the Schweizerisches Bundesamt für Umwelt, Wald und Landschaft

(Swiss Federal Office for Environment, Forests and Countryside) [9].

2.7. Secondary Raw Materials [10]

The demand for raw materials and energy has risen steadily with advancing industrialization and growing demand for products and goods, together with the increasing world population. As world population has increased since 1900 from ca. 1.5×10^9 to ca. 6.2×10^9 people in 1980 – that is, by a factor of about 4.1 – energy consumption has risen by a factor of 15; steel production by a factor of 20; the production of typical commodity metals zinc and copper by factors of 15 and 18, respectively; and the production of the rather novel metals nickel and aluminum by factors of 100 and 3000, respectively.

Aside from the production of consumer materials and goods from natural raw materials, the reprocessing of residues and wastes is becoming increasingly important. The return of materials into the material cycle is called recycling, and the substances which are recycled are known as secondary raw materials. The important aspects of recycling are

1) Conservation of natural resources
2) Reduction of total energy consumption
3) Reduction of the disposal site volume required

The reuse of valuable resources has a long tradition, activities being centered on metals. Examples are the remelting of noble metals such as gold and silver, the traditional processing of scrap iron and scrap nonferrous metals, and the processing of high-content metal dross, sweepings, ashes, dusts, etc. The recycling ratios of metals are therefore also distinctly higher than those of other materials, as shown in Table 4,

Table 3. Specific emissions of various means of transportation (g km^{-1} t^{-1}) and corresponding energy consumption [9]

	Rail	Truck	River boat	Sea-going vessel
Particles	0.006	0.080	0.038	0.011
CO	0.011	0.398	0.220	0.004
HC	0.069	0.199	0.055	0.035
NO_x	0.041	0.995	0.384	0.026
SO_2	0.081	0.080	0.165	0.234
Energy consumption, MJ km^{-1} t^{-1}	0.117	0.850	0.470	0.200

Table 4. Rate of recycling in the Federal Republic of Germany in 1989

Plastics	8 100	500	6

* Without internal recycling.
** Basis: production in 1988 including cast iron.

with the Federal Republic of Germany as an example.

Energy saving is a decisive factor, especially in the recycling of metals from scrap, since the expensive energy of reduction has already been provided and only the usually low energy melting must be expended again. To produce a marketable grade, refining or realloying may still be necessary. Figure 3 compares the energy requirements of metals from primary and secondary production.

Figure 3. Energy requirements of metal production from primary and secondary raw materials

The essential goal of conventional recycling is the recovery of valuable substances from relatively high-grade residues. The overall "*conventional recycling*" system can be described as follows:

1) The value of the recovered materials or substances exceeds processing costs
2) Recycling is carried out mainly within the process or the industry concerned
3) Considerable quantities of residues of complex composition exist, since the selection of materials and the design of goods have been solely production or application orientated
4) An overall economic – ecological concept is lacking.

Especially in highly industrialized countries, extensive, complex environmental protection legislation requires – aside from the use of efficient waste gas and wastewater purification systems – the conservation of natural resources and, to the greatest possible extent, the avoidance of residues and wastes (→ Legal Aspects, Chap. 2., → Legal Aspects, Chap. 3., → Legal Aspects, Chap. 4.). This has led to the development of new technologies especially suitable for processing industrial residues. For a modern raw materials industry with integrated recycling, therefore, some additional key features apply to the so-called *new recycling*:

1) The environment is incorporated in national economic thinking as a resource to be conserved.
2) Residues are also processed whose processing costs exceed the value of the recoverable components.

3) Recycling is not limited to the industry that produces the residue but is also carried out in other or new established sectors of industry.

Examples of this kind of recycling are the processing of salt slag from the secondary aluminum industry; the processing of zinc-containing filter dust from electrosteel works; the regeneration of used foundry sand; the use of building rubble and slag in civil engineering; the processing of electronic scrap; and the dismantlement of automobiles, household appliances, and other consumer goods. An important precondition for raising the recycling ratios for raw materials from vehicles and appliances is a "recycling-friendly" choice of material and design, a task to which designers and producers are increasingly dedicating themselves.

3. Oil, Gas, and Coal

3.1. Introduction

For millions of years, oil, gas, and coal have been parts of our natural environment. Thus, special environmental protection problems are not expected in connection with the natural occurrence of these substances, nor have they occurred. Only when these materials are used by humans must environmental protection be taken into account: special environmental protection measures are necessary during exploration, production, transportation, storage, processing (→ Oil Refining, Chap. 4.) and use (→ Heating Oil, Chap. 1.6.; see also → Automotive Fuels, Chap. 8.) of these materials and the products obtained from them. Special dangers arise because these materials and their associated substances can form easily flammable mixtures with air. A series of spectacular accidents have shown that at all stages of processing – from the well to the consumer – warning and accident prevention plans must be drawn up in agreement with the authorities and emergency services. Some constituents of these substances and of the products obtained from them are considered environmentally hazardous in the widest sense, and in some cases they are classified as harmful to humans and animals (e.g., carcinogenic [11], mutagenic, or teratogenic) or as substances dangerous in water [12].

For some years, protection of the earth's atmosphere worldwide has been considered one of the greatest ecological challenges. In the scientific discussion, methane [13] present in natural gas and carbon dioxide [14] formed by combustion of oil, gas, and coal play a special part. Within the United Nations, a framework climate convention has been signed by more than 150 governments [15].

3.2. Oil

3.2.1. Exploration

Exploration is carried out by seismic reflection surveying of potential structures after promising areas have been selected by geological studies (→ Oil and Gas). In the surveying, which is carried out with heavy equipment, sometimes even in impassable terrain, the reflections of shock waves are analyzed. The shock waves are generated by vibrators, falling weights, or explosions in 10 to 20 m deep boreholes or by pressure pulses in water. In inhabited areas, the effects of noise and vibration on the population must be minimized. Cultivated areas must be recultivated and the farmers and foresters compensated.

If the result of these geophysical studies is positive, an exploratory well provides final confirmation of the presence of a reservoir; this is then explored further and developed by subsequent wells. If reservoirs must be opened up below towns, military exercise terrain, or areas that have to be protected for environmental reason, this can be done by "directional drilling" from less sensitive locations (→ Oil and Gas). Sometimes one location is sufficient. The same applies to the development of offshore fields from a platform (Fig. 4). Pollution control of seawater in the case of offshore wells in coastal waters is particularly sensitive ecologically. All wastewater, superfluous drilling mud, and drill cuttings must be collected in a barge, transported to land, and processed before the residues are then dumped.

3.2.2. Production

The legal framework governing oil production differs greatly in different countries. Whereas in

Figure 4. Directional drilling in the Schwedeneck See Oilfield in the German Baltic Sea
a) Oilfield; b) Platform; c) Directional drillings; d) Coast; e) Baltic Sea

highly developed Western countries a multiplicity of laws (on nature protection, soil protection, water pollution control, immission protection, and occupational safety, as well as mining regulations) accord high priority to ecological goals, in the countries of the Third World in the absence of legislation, responsibility for the environment falls to the development companies. The highest environmental standards apply to drilling and production platforms for offshore production, especially near the coast (Gulf of Mexico, North Sea, Baltic Sea) since particularly sensitive ecosystems can be threatened here (Wattenmeer). In particular cases, both feces and rainwater must be completely captured and disposed of on land.

On its way from the earth's surface to the oil field, the well is sunk through a series of strata and groundwater horizons. The oil and its mineral, aqueous, and associated gaseous substances must be guaranteed not to penetrate into these strata and groundwater horizons during extraction. Furthermore, the groundwater horizons themselves must not be brought by the well into contact with other horizons or strata. This is achieved by casing the hole and continuously sealing the outside by injecting cement (→ Oil and Gas, Chap. 3.3.). Production occurs through additional riser pipes in the hole.

On *abandoning production* and shutting down operation, the holes must be filled and the processing site recultivated. These measures are usually carried out on the basis of plugging plans approved by the mine inspectorate. If, at this time, oil contamination of soil or groundwater is observed in the area of the processing site, remedial action must be carried out according to a previously drawn-up plan. The improvement achieved thereby must be followed by analysis of soil and water samples, and completion of the action must be documented.

3.2.3. Transportation

Normally, a series of production locations can be found in an onshore oil field. From these production locations, oil flows in pipelines to collection points. In inhabited areas, these pipelines are laid in the ground and – for safety reasons – covered with at least 1 m of soil and protected against damage by means of concrete slabs or protective tubes if required. Steel lines are coated with plastic and provided with cathodic corrosion protection.

After being processed in central processing plants (see Section 3.2.5), the crude oil is transported further by land (usually by steel pipeline) to the port of loading and unloading or to a refinery near the consumer. Ecological questions have an increasing influence on the route, because both the pipeline and the refilled pipe ditch can affect the microclimate: e.g., the usual sand bed in the pipe ditch causes undesirable drainage of moist biotopes.

In some cases, special environmental protection measures are necessary: e.g., double-walled pipelines in sensitive areas or leading a heated and insulated crude oil line over several thousand kilometers on stilts in order to keep the crude oil liquid and pumpable but not thaw permafrost soils and thereby upset the sensitive balance of nature (Alaska).

Pipelines require regular *monitoring, testing, and maintenance*. During operation, pressures and flows are monitored at several points on the line. If the deviation of the actual value from the target value exceeds defined limits, the line is shut down and depressurized. The line is inspected regularly by patrolling on foot or by flying over with helicopters in order to ensure regular monitoring, for example, if excavation works are carried out in the vicinity of the line. The line is tested at regular fixed intervals by pressure tests and by running through with cleaning scrapers, and condition monitoring by intelligent scrapers developed especially for this purpose. Maintenance of the measurement and control equipment and of the safety and shutoff valves should be carried out according to a fixed maintenance plan.

In individual cases, for smaller fields, transportation can be made by road tankers or railroad tank cars to the refinery or, in the case of offshore fields near the coast, by lighters (double walled for environmental reasons). Sea passages over great distances are carried out in special large tanker vessels (very large crude carriers, VLCCs) between the loading ports of the producing country and the unloading piers of recipient countries. Tanker vessels have single-walled construction: after a series of serious oil accidents at sea, transportation in double-walled vessels has increasingly been demanded since the early 1990s.

3.2.4. Loading and Storage

During the *loading* of processed crude oil into road tank trucks, railroad tank cars, lighters, or oceangoing ships, as well as during the filling of storage tanks, environmental protection measures should be used to protect soil, bodies of water, and air from contaminants: filling operations must be monitored with alarm and cutoff devices; pumps have to be installed in an oil-collecting trough; and air pollution by volatile hydrocarbons must be minimized by gas displacement and gas recycling systems.

The oil can be *stored* in abandoned salt mines, salt caverns, granite caverns (Sweden), and caverns in permafrost soil or in tanks aboveground. For storage in steel tanks, a double tank bottom is increasingly required. The tanks must stand in an oiltight, oil-collecting trough or tank bund or must have a double wall. Floating roof tanks have to be provided with especially effective edge seals or be constructed as fixed roof tanks with internal floating ceilings.

3.2.5. Processing

The crude oil that emerges from the well is contaminated with minerals, water, and gas, which must be separated (→ Oil and Gas, Chap. 3.4.3.1.). The separated *aqueous constituents* with their dissolved salts are reinjected into the reservoir and in this way disposed of while preserving the environment and maintaining pressure.

Depending on local conditions, the separated *gas* is flared, reinjected into the reservoir, or – after treatment – used for energy generation. Flaring has to be deprecated for environmental reasons. Further processing of crude oil is carried out in oil refineries (→ Oil Refining), where

it is processed to motor fuels, combustibles, and chemical raw materials.

Upon combustion of the refinery products, *sulfur compounds* present in the crude oil will be oxidized to sulfur oxides (mainly SO_2). To protect the environment, these compounds are increasingly being removed from the individual intermediate products by hydrogenation and reduced to hydrogen sulfide. Hydrogen sulfide is processed in Claus plants to elemental sulfur (→ Sulfur, Chap. 6.3., → Sulfur, Chap. 6.4.), which is stored and transported to end users (usually as a liquid). For environmental protection reasons, downstream of the Claus plants, tail gas plants are connected which guarantee that 99 % of the hydrogen sulfide is converted to elemental sulfur (→ Natural Gas, Chap. 2.7.1., → Natural Gas, Chap. 2.7.2.).

Nitrogen-containing compounds present in crude oil are hydrogenated in the aforementioned process to ammonia and fed together with hydrogen sulfide to the Claus plant. Here, ammonia is converted largely to elemental nitrogen.

Organometallic compounds present in crude oil remain in the heavy fuel oil or the petroleum coke. When these fuels are burned the metals remain in the ash – as oxides, sulfates, etc. – or in the flue gas (flue-gas scrubbing is therefore necessary).

3.2.6. Uses

The main constituents of all petroleum products are hydrocarbons, which are used as motor fuels, combustibles, and chemical raw materials. These substances and the products arising from them burn to water and carbon dioxide:

$$C_nH_{2m} + xO_2 \rightarrow nCO_2 + mH_2O$$

The carbon dioxide produced during combustion is a "greenhouse gas" that is judged by some scientists and governments to contribute substantially to global warming. In 1991 a national program for CO_2 reduction was started by the government of Germany. A reduction of 25 – 30 % between 1987 and the year 2005 was fixed as a target, and a catalogue of measures was laid down. From this, a reduction of CO_2 emissions of about 300×10^6 t is expected. The effectiveness of this measure is estimated to be slight, because the building of coal-based power stations in China alone in one year counterbalances German reduction measures. An internationally coordinated policy is therefore being aimed at.

Used *engine and gear oils* were previously disposed of by burning. Today these materials are increasingly reprocessed because legislation in some countries prohibits burning and requires recycling. The reprocessed materials then come onto the market as secondary raffinates.

In the use of *motor fuels,* special emission reduction measures are required for reduction of the environmental pollution caused by road traffic).

3.2.7. Cost

In the case of environmental protection costs, a distinction generally is made between the pure investment for environmental protection and the environmental protection operating costs. A large part of the environmental protection costs results from legal requirements. These regulations require observance of "generally recognized engineering standards" or the "state of the art.". The environmental protection operating costs excluding capital costs of the refineries of the EC states for 1998 have been estimated at about 2 to 10 ECU (European Currency Units) per tonne of product, depending on the state [16]. The environmental protection operating costs of the German petroleum industry, including service of capital, have been determined for 1987 and 1989 as about € 5.6/t in each case [17].

3.3. Gas

Natural gas and petroleum belong to the same class of substances: both are hydrocarbons (→ Natural Gas) and in almost all cases occur together in nature. Exploration and production are therefore carried out in the same way as in the case of oil (see Sections 3.2.1 and 3.2.2). Special environmental protection and safety measures are necessary in case of sour gas occurrences, since the hydrogen sulfide they contain is toxic to humans, animals, and plants. For production from such wells, subsurface safety valves (SSSV), which are installed from 30 – 100 m below the earth's surface or below the seabed, are a

proven technology. In the course of production, soil subsidences may occur, which can make special measures necessary in flat country to protect bodies of water.

3.3.1. Processing

The natural gas produced is processed at the well locations. The undesirable solid constituents, reservoir water, and heavy hydrocarbons are separated and the off-gas is sweetened to remove any hydrogen sulfide and carbon dioxide and dehydrated to avoid corrosion in the process installations connected downstream (→ Natural Gas, Chap. 2.3., → Natural Gas, Chap. 2.4.).

Some gases contain small amounts of mercury, which require further processing since this substance is hazardous to health and therefore must be removed (→ Natural Gas, Chap. 2.3.2.).

3.3.2. Transportation

Natural gas is transported at high pressure in steel pipes laid below ground or in liquid form by special ships as liquefied natural gas (LNG) (→ Natural Gas, Chap. 3.5., → Natural Gas, Chap. 4.1.). In ecologically sensitive or especially valuable areas (Wattenmeer, other biotopes, rivers, and roads), the pipelines can be laid by trenchless technology or horizontal drilling. Monitoring, testing, and maintenance are carried out similarly to oil pipelines (see Section 3.2.3).

3.3.3. Storage

Large amounts of gas are stored underground. For this purpose, natural porous reservoirs and artificial salt caverns can be used (→ Natural Gas, Chap. 4.2.). No special environmental considerations apply in the operation of these reservoirs. During creation of the salt caverns by solution mining, environmentally acceptable disposal of the saline brine must be ensured.

3.3.4. Uses

Natural gas consists mainly of methane (→ Natural Gas, Chap. 1.1.). It is used as a source of energy and a chemical raw material. Both methane itself and the carbon dioxide produced during its combustion are climatically active gases, i.e., they absorb and reemit thermal radiation and so contribute to the greenhouse effect. Different calculations exist which [14] characterize the effectiveness of various greenhouse gases. The data available in the literature deviate greatly from each other, because much detailed knowledge is lacking and many effects have still been inadequately explained. Thus, for example, the lifetime in the earth's atmosphere of the gas molecules relevant to climate is subject to considerable uncertainty.

To minimize the greenhouse effect of the gases mentioned, in the case of *methane* the transport, storage, and distribution of natural gas must be as nearly loss-free as possible. *Carbon dioxide emissions* from the combustion of natural gas can be reduced by increasing the overall efficiency of heat production by technical improvements of the firing installations, combined heat and power schemes, and other energy saving measures. To hasten these savings, in various countries reduction programs have been drawn up or the introduction of taxes ("carbon tax") has been considered.

3.3.5. Cost

The costs of a carbon dioxide limitation (stabilization of emissions in the year 2010) are estimated for the United States as ca. $ 10^{12} [13].

3.4. Coal (→ Coal) [18][19][20]

3.4.1. Mining Engineering

Mining plants need large surface areas for their installation. In planning new mines, hauling shafts and coal preparation installations of existing mines are used as much as possible.

Underground mining of coal causes damage at the surface. Mining damages include subsidence, dislocated inclined planes, stretch, and wrench faults. Subsidence changes the slope of rivers and causes the formation of swamps, fissures in buildings, and thresholds in streets. Mining dam-age may be minimized by application

of underground replacement techniques (refilling the cavities with waste rocks or washery tailings).

The *open-cast mining* of coal often requires drainage of the seam and overlying strata. Since open-cast mining may reach depths of 600 m, lowering of the groundwater level in areas adjacent to the mine is also necessary to stabilize the scarp of the mine. For this purpose, wells are installed at the border of the mine and at the entrance area of the groundwater, these wells are arranged to galleries. Modern surface mining techniques demand not only full mechanization with high efficiency (excavators, etc.) but also extensive automation of the sequence of work. The current mining technique using an equipment system consisting of bucket–wheel–excavator, conveyor belt and stacker has a performance of some 100 000 m^3/d. The relation of removed soil to coal (stripping ratio) increases with depth of 700 – 1100 m from about 3 to 5 m^3/t. The removed waste material is used directly for replenishment of the coal-spent area and reclamation.

3.4.2. Processing

Coal normally cannot be mined as clean coal. Run-of-mine coal is generally associated with different amounts of mineral matter. For some purposes, especially power and heat generation, coal may be used directly as so-called ballast coal. However, since mineral matter associated with coal has a considerable negative environmental impact (see Section 3.4.3), preparative measures must be used to separate the mineral matter from the coal. Preparation of coal is thus a primary measure of environmental protection, which separates a major part of harmful components (sulfur, trace elements) from the coal at convenient cost. Preparation lowers the pyrite sulfur level of the run-of-mine coal; separation of organically bound sulfur is not possible with the usual mechanical preparation methods. Pyrite crystals are intergrown with coal to different degrees. To obtain separation, coal must be crushed to grain sizes that correspond to the grain sizes of pyrite. This becomes more difficult the finer the pyrite grains and their distribution within the coal are. An extensive separation of pyrite from coal is connected with a lowering of the amount of the trace elements lead, cadmium, copper, and zinc in coal. The concentration of the trace elements – arsenic, barium, lead, cadmium, chromium, copper, mercury, strontium, and zinc – in the preparation waste increases with increasing ash content of the preparation wastes. Traces of beryllium, cobalt, molybdenum, vanadium, and nickel are bound to the organic matter itself.

Dust emissions resulting from preparation measures are decreased by filtering air and suffocating vapors. The amount of *wastewater* that leaves the preparation installation can be kept low by intermediate cleaning and reuse of part of the water from the preparation. Wastewater from the preparation installation is usually led to clearing ponds. For the elimination of flotation wastes, the deposition of washery tailings on dumps is mainly used. By special construction of the dump, oxidations processes (occurring especially with pyrite) can be suppressed to a great extent, thereby preventing the mobilization of heavy metals.

3.4.3. Utilization

Coal is used as a raw material in coal conversion processes, which can be divided into three main groups (see Fig. 5):

1) Mechanical conversion, including coal preparation and briquetting
2) Processes to obtain secondary fuels, including coking, gasification, liquefaction, and combustion
3) Other processes for the generation of energy (e.g., absorption on active coke and active carbon) including the recovery of byproducts (e.g., benzene, phenols)

Coal is an organic rock, consisting of two essential parts: the organic and the inorganic (mineral) matter. Its components may affect the environment in a typical manner during coal utilization. According to the particular conversion process, different products are formed in different quantities.

The *mineral matter*, which is termed ash or slag, may be used in commercial products. The main portion of trace elements present in coal is bound to the mineral matter, especially the sulfidic components. Care must be taken that these

Figure 5. Utilization of coal

trace elements are not released uncontrolled into the environment.

The aforementioned environmental influences are introduced directly by the coal into the corresponding processes of utilization and valorization. Many other products that affect the environment are formed during conversion itself.

Figure 6. Development of world coal consumption

Heat and Energy Production. In the combustion processes used essentially for the production of electric power and heat, CO_2 is a climate-influencing emission, as are SO_2 and NO_x (including N_2O). In unfavorable conditions, toxic compounds may even be formed; a representative example is dioxin.

The development of world coal consumption in petajoules is shown in Figure 6. Consumption is expected to increase only slightly by about 2 % per year in the near future. That means that in the next few years, coal consumption will not exceed 100 000 PJ.

To avoid or reduce environmental problems, fundamental knowledge must be obtained for the development and optimization of technical processes. The main product formed by coal combustion for heat and electricity production is CO_2. As depicted in Figure 7, 3 t of CO_2 results from 1 t of hard coal, that is 1500 m^3 of CO_2. Worldwide coal consumption of 100 000 PJ will result in the generation of 10^{16} m^3 CO_2. Since the CO_2-free combustion of coal is not envisioned, emphasis must be placed on strategies of avoidance (i.e., economical use of energy ressources, as well as an increase in efficiency, which is demanded of engineering). By gas and steam processes, efficiencies of more than 50 % appear possible. A corresponding reduction of SO_2 and NO_x can be expected from increasing the efficiency of combustion.

The specific coal consumption for energy generation has been reduced from 1200 to 300 g/kW · h today by technical progress, and by more efficient dust precipitation, dust emission has been lowered from 800 to 50 mg per cubic meter of flue gas. At the same time the emission of detrimental matter bound to particles (trace elements, polyaromatic hydrocarbons, etc.) has decreased accordingly.

Emissions from coal combustion can be reduced by primary and secondary measures (Fig. 8). Primary measures include coal preparation, special arrangements at the dust entry (e.g., in a cyclone), improvement of the firing system, lowering of combustion temperature and

shortening of combustion time, flue-gas recycling, and eventually the use of additives, which may reduce the emission of dust, SO_2, NO_x, HCl, and HF as well. Yet all of these primary measures together are usually not sufficient, to meet the demands of environmental protection. Accordingly, secondary measures must also be involved in the processes. These are, in terms of the flue gas, mainly the precipitation of dust, but also include gas cleaning by desulfurization and DENOX processes (→ Fixed-Bed Reactors, Chap. 3.). In terms of heat, overall reduction of noxious emissions may be reached by increasing efficiency and better utilization of waste heat.

Figure 7. Amount of CO_2, SO_2, and NO_x formed during combustion of 1 t of coal

The schematic of a wet flue-gas desulfurization process, employed for some years in an electric power and heat generating plant in Germany, is shown in Figure 9. Wet washings for desulfurization are accomplished with lime or suspensions of limestone at a temperature near the dew point of the flue gas. The washing liquids are recycled. The best degrees of desulfurization are obtained with hydrate of lime; slaked lime is diluted before entering the absorber (c). The ratio of sprayed liquid and gas to be cleaned is usually between 3 and 10 L/m^3. The absorbent is added in about stoichiometric ratio, because of stoichiometric reaction with the noxious gas (molar ratio Ca: S = 1). Flue gas and washing liquid move countercurrently. The flue gas is thus mixed with finely distributed lime absorbent and sulfur dioxide is dissolved in the washing liquid before it reacts with the absorbent. The contacting time between gas and liquid is ca. 5 min. Part of the washing liquid flow is led to an oxidation stage (f), which is mostly integrated into the washery sump. The calcium sulfite formed is oxidized here to calcium sulfate. From this partial flow the utilizable end product gypsum is brought out, which is crystallized on added crystallization nuclei. Downstream of the absorber, the flue gas has to be reheated to 100°C before it is led to the chimney. Elimination degrees for sulfur dioxide of more than 85 % are obtained with this process, i.e., concentrations of <400 mg SO_2 per cubic meter in the cleaned gas.

On a technical scale, NO_x diminution in the flue gas is achieved by selective reaction of NO_x with added ammonia in the presence of a solid catalyst (DENOX process). Nitrogen oxides are reduced thereby to water and nitrogen in the presence of oxygen. The elimination of NO_x occurs at 300 – 500°C. Titanium dioxide or vanadium pentoxide can be used as catalyst (Fig. 10).

Another technique for desulfurization and denitrogenation is the so-called activated carbon process. Flue gas is led to an absorber stage where SO_2 is absorbed by activated carbon. NO_x is converted to N_2 with 80 – 90 % yield.

The success of SO_2 reduction due to the introduction of flue-gas desulfurization can be seen in Figure 11. In the Federal Republic of Germany, emission of SO_2 was reduced from about 900 000 t/a in 1983 to <100 000 t/a in 1989. The same is true for NO_x emissions, which were reduced by DENOX installations from about 500 000 t/a in 1983 to less than 100 000 t/a in 1992 (Fig. 12). If this reduction could be achieved worldwide when utilizing coal for the generation of electric power and heat, it would be an eminently important contribution to the protection of the environment. The processes are available, but introduction of these techniques often fails because of an unwillingness to invest in environment protection.

Coke Production. The second largest use of coal production after the generation of electric power and heat is in the production of coke. Cokefaction is also connected with environmental impacts, especially gaseous emissions, as

Figure 8. Measures for reduction of emissions formed during combustion of coal

Figure 9. Schematic of a wet flue-gas desulfurization process
a) Electric precipitator; b) Prewasher; c) SO_2 absorber; d) Regenerator; e) Lime preparation station; f) Oxidator; g) Settling tank; h) Compressor; i) Gypsum buffer container; j) Gypsum dryer; k) Gypsum deposit

well as charging of wastewater. Avoiding emissions from a coking plant is especially difficult because of its large-faced construction. Since the installations stand in the open air and many sources of emissions are distributed over a large area, enclosing them is difficult. Moreover, these diffuse sources (leakages) are related to operations such as filling, pressing, quenching, classifying, and so on. The type and quantity of emissions depend on various influences that occur during cokefaction at various points. Some points and types of emission, as well as limit values and measures that minimize environmental impact, are given below.

Figure 10. Schematic of a DENOX plant
a) Steam generator; b) Preheater; c) Dust precipitator; d) Flue-gas desulfurization plant; e) Heat exchanger; f) Heater; g) DENOX unit; h) Chimney

Figure 11. Reduction of SO_2 emissions in the Federal Republic of Germany

Point and type of emission	Limit values and preventive measures
Combustion gas	total sulfur $<0.8\,g/m^3$
Flue gas	NO_2 $<0.5\,g/m^3$ (5 % O_2)
Filling	dust $<25\,mg/m^3$
Cooling	dust $<20\,mg/m^3$

The wastewater of coking plants with wet quenching is alkaline (pH 8.5 – 9.5); it contains ammonia, phenols, sulfur, sulfanes, and cyanides. It must be rid of special contaminants before delivery to the purification plant. Intensively smelling substances such as mecaptans are separated from wastewater. In addition to the elimination of toxic components (phenols and cyanides), oils and tars must be separated.

For the elimination of organic compounds, biochemical processes, extractions, absorption by activated coke, and combustion of wastewater are well suited. Some modern coking plants use the dry coke cooling process in which problems with organic componds no longer occur.

Coal Valorization Processes (Gasification and Liquefaction). Particularly in the case of *gasification* (→ Gas Production, Chap. 4.), emissions may really affect the environment during sluicing of material streams, especially of residues. Environmental pollution may also originate from flue dust in the raw gas, the raw gas itself, and the process water. The same sub-

stances are found here as in combustion processes, and the techniques of diminution are essentially the same. Another problem is that these residues cannot be deposited in an environmentally protective manner without more ado, especially in the case of alkaline catalysts. A solution could be to introduce a stage of inertization before deposition, for example, thermal treatment. The developments required are similar to those for power station byproducts.

Figure 12. Reduction of NO_x emissions in the Federal Republic of Germany

Figure 13. Reduction of residues formed during coal liquefaction by subsequent gasification of the residues

In the case of *coal liquefaction* (→ Coal Liquefaction), e.g., in liquid-phase hydrogenation, damage to the environment can be minimized and easily controlled because of the closed system. The formation of phenols – which formerly was a problem – and the environmental problems caused thereby may be avoided by appropriate operating conditions. The compounds H_2S and NH_3 contained in process water and gas can be eliminated without any problems. Only elimination of the mineral residue of hydrogenation in an environment-protecting manner remains. One may proceed here in the same way as suggested for gasification residues.

The combination of liquefaction and subsequent gasification of the liquefaction residues at 1500°C does not produce more than ca. 10 % ash, which is inert and ready for deposition (Fig. 13).

4. Renewable Resources

Renewable resources are animal and vegetable resources (biomass) that are used as energy carriers or raw materials in the widest sense. The term "renewable" means that the biomass of the agricultural ecosystem on average "survives," i.e., it is used only to the extent that it is regenerated. Agricultural ecosystems are therefore not of themselves lasting; rather, the conditions for their persistence are protection of the ecosystem and abandonment of predatory exploitation.

4.1. Significance

Renewable resources were for centuries virtually the only energy carriers and resource base for chemical products. Although in the 19th and 20th centuries they were driven back, first by coal and later by petroleum, they have never completely lost their importance for chemistry, because many of the structures and properties provided by nature are difficult, uneconomic, or practically impossible to reproduce in a chemical synthesis. Examples are the drying oils, with their importance for paint raw materials, or cellulose with its ethers and esters with inorganic and organic acids.

Renewable resources received greater attention again after the oil crises of the 1970s had made clear the dependence on petroleum and the limited nature of oil reserves. In the recent past, environmental reasons have been added as a motivation for renewed interest in renewable resources, since evidence exists that the global CO_2 balance is affected significantly by burning fossil energy carriers. In addition, this discussion also plays a part – although a considerably less important one – for chemical raw materials and their participation in the carbon cycle.

Not to be underestimated is the fact that many industrialized countries are running short

of space for waste disposal. For this reason, the possibilities of waste disposal, especially of plastics and packaging materials, via composting are being discussed increasingly. Biodegradable materials from renewable as well as fossil resources may make an important contribution here.

Finally, agricultural policy reasons exist for using renewable resources. The cultivation of plants that provide raw materials usable for energy production or internal combustion engines ("energy plants") or for the chemical industry ("industrial plants") has been publicized by agricultural interests, especially in countries with excess production, such as the EU countries. The possibility is seen here of cutting back excess production and yet keeping useful agricultural land alive.

The cultivation and use of renewable resources have been encouraged on national and European levels with the aid of subsidies and tax reliefs, and their political importance has thus been emphasized.

Within the framework of the Altener program [21,22], the proportion of regenerative energy (in which biomass is included) to total energy consumption within the European Union is to be increased from 4 to 8 % by the year 2005, for example, with EU grants.

In Germany renewable resources are encouraged on the national level via the " Fachagentur Nachwachsende Rohstoffe" ("Special Agency for Renewable Resources"). The purpose of this institution is to seek practical opportunities for increased application of renewable resources via improved coordination among the government, science, and industry.

4.2. Important Renewable Resources

Table 5 (modified according to [23]) surveys the quantitatively most important sources of renewable resources.

In the renewable resources used by the chemical industry, natural fats and oils play the most important part. Table 6 shows the estimated consumption of various groups of resources by the chemical industry [24].

4.3. Industrial Use

Industrial application relates above all to use in the chemicotechnical field, where renewable resources are used for the production of intermediate and end products. The most important product lines from renewable resources are based on fats, oils, starch, sugar, and cellulose.

4.3.1. Natural Fats and Oils

World production of natural fats and oils has increased steadily in the last decades and in 1990 reached ca. 80×10^6 t [25,26]. Vegetable oils, at 60.7×10^6 t, make up the main part, but animal fats (20×10^6 t) also occupy an important place in oleochemistry, especially in the utilization of inedible tallow and fat. In all, probably ca. 14 % of world fat production is used chemically [24, 26], ca. 80 % for human food, and the remaining 6 % as feed material. Castor oil is an exception: because of its unpalatability and special structure it is used exclusively for industrial purposes, mainly for paint raw materials and plastics (e.g., polyamide 11). The 1990 production figures for the most important oils and fats (in 10^6 t) [26] are listed below; for further information also regarding composition, see → Fats and Fatty Acids.

Soybean oil	16.5
Palm oil	10.8
Rapeseed oil (erucic acid free)	8.1
Sunflower oil	8.0
Cottonseed oil	3.8
Peanut oil	3.7
Coconut oil	2.8
Olive oil	1.8
Palmkernel oil	1.3
Linseed oil	0.7
Castor oil	0.4
Others (corn, sesame, etc.)	2.8
Vegetable oils, total	60.7
Tallow, lard	12.3
Butter	6.3
Fish oil	1.4
Animal fats, total	20.0
Total	80.7

Table 7 (after [24]) surveys the most important fields of application of oleochemical products.

Table 5. Important renewable resources

Cellulosecontaining resources	Starchcontaining resources	Sugarcontaining resources	Oilcontaining resources
Wood	potato	sugarcane	rape
Straw	corn (maize)	sugar beet	flax
Hulls/shells	grain	fodder beet, etc.	soya
Bagasse *	cassava	sweet sorghum	sunflower
Cotton		molasses	oil palm
			coco palm
			castor-oil plant
			peanut
			cotton

* Wastes from cane sugar production.

Table 6. Present use of natural raw materials (in 1000 t) by the chemical industry, estimated

Raw material	Germany (excluding former German Democratic Republic)	EU	World
Oil and fat	700	2700	9500
Cellulose	220	600	5000
Starch	115	390	1750
Sugar	15	65	800

Table 7. Most important fields of application of oleochemical products

Product	Application
Fatty acids and derivatives	metallic soaps, detergents, soaps, cosmetics, alkyd resins, paints; textile, leather, and paper industries; rubber, lubricants
Fatty acid methyl esters	cosmetics, detergents
Glycerol and derivatives	cosmetics, toothpaste, pharmaceuticals, foods, paints, plastics, synthetic resins, tobacco, explosives, cellulose processing
Fatty alcohols and derivatives	detergents, cosmetics; textile, leather, and paper industries; duplicator stencils, petroleum additives
Fatty amines and derivatives	fabric softeners, mining, road building, biocides, textile and fiber industries, petroleum additives
Drying oils	paints, varnish, linoleum
Castor oil, ricinoleic acid	polyamide 11, alkyd resins

Alkyd resins (→ Alkyd Resins) are produced on a large scale from natural triglycerides and the fatty acids made from them. Soybean oil is the most significant in this connection as the most important (semi-) drying oil. Linseed oil, which was previously dominant in the production of alkyd resins, is currently used mainly in the manufacture of linoleum.

The most important conversion reactions and products are shown in Figure 14 (according to [26]).

Surfactants. After soaps and petrochemically produced linear alkylbenzenesulfonates, fatty alcohol ethoxylates are the most important surfactants, as measured by consumption in Western industrialized countries (→ Surfactants, Chap. 14.) [27]. Fatty alcohol ethoxylates figured in public debate, being raw materials for fatty alcohol ether sulfates. Fatty alcohol ether sulfates play a large part in cosmetic formulations. Under the acidic conditions of their production by sulfation, traces of dioxane (a suspected carcinogen) can appear as a degradation product of the polyether chain (→ Surfactants). Today, process technology measures enable the dioxane content to be lowered to less than 10 ppm [28].

For nonionic surfactants, greater consideration of exclusively natural structural elements can be expected in the future. Here, the new alkyl polyglucosides, in particular, are interesting for cosmetic applications because of their mucous membrane compatibility, low toxicity, and easy biodegradability [26, 29] (→ Surfactants).

The potential for renewable resources in the surfactant field is increased further by the combination of oleochemical and carbohydrate structural units. A survey of existing carbohydrate surfactants, their significance, and their properties is given in [29]. For a short description of fatty acid esters of sorbitol and sucrose, see → Surfactants, → Surfactants.

Rapeseed oil has recently acquired practical importance as a *noncirculating lubricant*. Mineral-oil-based lubricants from motor saws lead to contamination of forest soil, which can be avoided by the introduction of rapeseed oil

Figure 14. Most important conversion reactions of natural oils and fats and products formed

products because of their rapid and complete biodegradability [30].

4.3.2. Cellulose and Its Derivatives

4.3.2.1. Cellulose

The chemical industry worldwide uses ca. 5.1×10^6 t of cellulose (dissolving pulp; EEC: 0.6×10^6 t, Germany: $>0.2\times10^6$ t). This constitutes about 3.5 % of the total cellulose production of ca. 150×10^6 t (1990 – 1991), of which the vast majority – more than 98 % – goes into "nonfood use" [31].

Cellulose is the most important product of chemical exploitation of wood ("chemical pulp"); between 30 and 50 % of hardwoods and softwoods consist of cellulose. A particular problem of this wood exploitation is association of the cellulose with lignin and hemicelluloses, each of which makes up 20 – 25 % of the wood.

As a result of the process for producing cellulose from wood, particularly the customary use of sulfur-containing compounds in the sulfite and the kraft (sulfate) processes, lignin and the hemicelluloses must be burned and thus can be utilized only for generation of process heat. A detailed survey of various pulping processes is given in [32] (→ Paper and Pulp, Chap. 1.3.).

Most of the world chemical pulp production (nearly 90 %) is produced by kraft (sulfate) pulping, in which lignin and hemicelluloses are dissolved out of the wood with an aqueous mixture of sodium sulfide, sodium carbonate, and sodium hydroxide solution (→ Paper and Pulp, Chap. 1.3.1.) [33]. The complicated bleaching with chlorine – hypochlorite or chlorine dioxide, which is required because of the dark color of the sulfate (kraft) cellulose, can lead to considerable environmental pollution because a number of organic, nondegradable, and unusable chlorine compounds are formed (→ Paper and Pulp, Chap. 1.6.1., → Paper and Pulp, Chap. 1.6.2.). Even though lower wastewater loads are definitely achieved with chlorine dioxide, reservations remain that – aside from the uneconomical size of the operating units – have led to shutdown of the kraft pulping process (e.g., in Germany).

The *sulfite process* [34], which is stagnating worldwide, is less polluting and is used on a large scale in Germany (→ Paper and Pulp, Chap. 1.3.2.). A few technical drawbacks must be accepted, however, particularly poorer mechanical strength of the (paper) cellulose so prepared; besides, only low-resin woods can be used as raw materials.

In a few processes, an attempt is made to avoid the problems associated with bleaching; examples are the ASAM process as a modification of the sulfite process (→ Paper and Pulp), and the Organocell (→ Paper and Pulp) and Acetosolv processes, which both work with organic lignin solvents, the Organocell process requiring ClO_2 [35].

Regenerated cellulose (cellophane), as obtained via alkali cellulose and the xanthate (produced from alkali cellulose by reaction with carbon disulfide), is easily biodegradable [36, 37] and permitted under food laws. Nevertheless, this product is declining as a film material since it is increasingly being replaced by polypropylene which is more resistant to mechanical stress and is considerably cheaper.

Detailed information on fibers from regenerated cellulose (viscose fibers) is given in → Cellulose, Chap. 3.1.

Regenerated cellulose, which is made by the copper oxide – ammonia (cuoxam) process in declining production volumes, is an important membrane material for dialyzers ("artificial kidneys") (→ Cellulose, Chap. 3.3.). Copper from the cuoxam process is almost completely recovered with ion exchangers. From an ecological viewpoint, the viscose process is inferior to the cuoxam process. The recovery rate for carbon disulfide used in the viscose process is ≤70 % (→ Cellulose, Chap. 3.4., → Cellulose, Chap. 3.1.4.).

4.3.2.2. Cellulose Esters

Inorganic Cellulose Esters. Cellulose nitrate, the oldest inorganic cellulose ester (nitrocellulose), has great importance as an explosive and a paint raw material, whereas the mixture with camphor is produced still as thermoplastic (celluloid) to a minor extent (e.g., for combs, table tennis balls, spectacle frames). The world capacity for cellulose nitrate amounts to ca. 165 000 t, with declining utilization.

Lacquers made from cellulose nitrate are excellent for open-pore wood (furniture) coatings, but usually contain considerable amounts of organic solvents [38].

For a description of safety aspects in the production, storage, and transport of cellulose nitrate, see → Cellulose Esters, Chap. 1.2.8. The potential hazard of cellulose nitrate depends on the degree of nitration and on the wetting with, e.g., ethanol or *n*-butanol (at least ca. 20 wt %). Since cellulose nitrate with high nitrogen content is explosive in the dry state, it may only be transported moistened.

Organic Esters. Of the cellulose esters of organic acids, acetic, propionic, and butyric acid esters, as well as the corresponding mixed esters (so-called acetopropionates and acetobutyrates), are especially important technically. The mixed ester of acetic and phthalic acid (monophthalate, from partially hydrolyzed cellulose triacetate and phthalic anhydride) is used to a small extent, especially in galenicals as tablet coatings for regulating drug absorption (dissolving first in the alkaline intestinal medium). For a short description of industrial uses of mixed esters, see → Cellulose Esters, Chap. 2.2.5.

For the production of moldings, thermoplastic cellulose esters of organic acids play a considerably greater part than cellulose nitrate, whose importance has diminished because of its flammability. Cellulose acetate and acetopropionate are important for spectacles (lenses and frames), sunglasses, and sports goggles, see also → Cellulose Esters, Chap. 2.4.9. [39].

During the debate on the biodegradability of plastics, especially packaging materials, thermoplastic cellulose esters have been studied in more detail. Cellulose triacetate proved to be not or not sufficiently rapidly biodegradable [40, 41]. However, the compostability of cellulose esters improves with decreasing degree of substitution. Cellulose-2,5-acetate ("secondary acetate") is apparently biodegraded slowly [41]. Cellulose diacetate, on the other hand, is designated compostable and is available as a commercial product, optionally also for food packaging [42], mixed with, e.g., citrate ester plasticizers that support degradation [43, 44].

Cellulose acetate butyrate (CAB) continues to be important in automobile metallic paints. As a result of the rapid viscosity increase of CAB-containing paints upon evaporation of organic solvents, and despite the very dilute solutions necessary to achieve planar orientation of the aluminum bronze, flawless processing is possible. Because of the high solvent emissions of such paint systems, considerable efforts are being made to replace them by waterborne metallic paints [45].

4.3.2.3. Cellulose Ethers

Cellulose ethers play an important part industrially. In 1987, world consumption – without the state trading countries – was 230 000 t and the EC share 116 000 t [46, 47], with a tendency to rise (for more detailed data see → Cellulose Ethers, Chap. 10.). The most important ethers are carboxymethyl cellulose (or its sodium salt) and methyl cellulose, which together make up more than three-fourths of the world consumption. The hydrophilic character of the cellulose ethers (hydrophilicity depending on the degree of substitution) leads to water-soluble products that are used as thickeners, water absorbers, and adhesives in the building industry; in surface

coatings (including methyl cellulose as a wallpaper adhesive); as an auxiliary and additive in detergents (largest use [47]); in foods, cosmetics, and pharmaceuticals; as paper and textile auxiliaries, in petroleum production; etc. Hydroxyethyl cellulose also, as the third largest product of this group, has similar fields of application but is not permitted as a food additive (→ Cellulose Ethers, Chap. 5.1.2.).

4.3.3. Starch

The mixture of amylose (essentially straight chain) and amylopectin (branched), occurring naturally as "starch," has a fluctuating percentage composition depending on its raw material source. The amylopectin fraction usually predominates (ca. 3/4) (→ Starch, Chap. 1.).

Table 8. Uses of starch in different industries

Branch of industry	Products	Starch content ∗
Paper manufacture	wrapping paper	3.0 – 5.0 %
	newsprint	1.5 – 2.0 %
	graphic paper	1.5 – 2.5 %
Paper processing	corrugated cardboard	10 – 14 g/m^2
	laminated paper	12 – 25 g/m^2
Building materials, etc.	gypsum plasterboard	5 – 7.0 %
	mineral fiberboard	3 – 6.0 %
	granulated coal	2 – 5.0 %
Chemistry, cosmetics, pharmaceuticals	washing starch	15 – 25 %
	washing powder	3 – 5 %
	washing raw materials	30 – 45 %
	toothpaste	6 – 70 %
	tablets, pills	0.5 – 3.0 %

∗ Based on dry matter.

Exceptions with a predominant amylose fraction are, e.g., starches from peas and high-amylose corn, grown especially for its high amylose content [48]. Since time immemorial, starch has been used outside the food field (e.g., as a paper and textile auxiliary). In total, ca. 500 000 t of starch are consumed annually in the industrial and technical fields in Germany (excluding the former German Democratic Republic) and more than 2×10^6 t in the EU. Its use in the chemical industry as a chemical raw material in the narrower sense, is considerably less [49], about 600 000 t in the EU [50]. Important applications are as an additive for building materials (e.g., in gypsum wallboards), cosmetics, and detergents, as well as an auxiliary for dyes and pharmaceuticals (→ Starch, Chap. 1.7.).

Table 8 shows the content and applications of starch in selected products in the chemicotechnical field [51].

Starch has recently attracted great interest as a blend raw material for thermoplastics, especially for packing materials, refuse sacks, or mulch films that are claimed to be biodegradable. Such degradation cannot occur in disposal sites, so only composting in appropriate systems is possible [52].

In the composting of blends of polymers customary in the packaging sector with starch, a macroscopically rapidly advancing degradation is initially achieved, based on microbial degradation of the starch contained in the blend. The thermoplastic component of the blend (e.g., polyethylene) is not completely degraded chemically despite the complete disappearance of the film or molding (→ Plastics, Recycling, Chap. 6.2.). This is clear from early product examples with degradation curves in which the weight loss is followed and only an asymptotic approach to a maximum value (= starch content) is visible [53, 54]. Thus, a final evaluation of the biological compostability depends also on the second blend component [e.g., polyethylene, ethylene – acrylic acid copolymer [55, 56], partially hydrolyzed poly(vinyl acetate) [57–59]. Increasing degradation of synthetic polymer blend components is aimed at with prooxidants [60]. Composting conditions are decisive for the chronological sequence of degradation. To overcome drawbacks in biodegradability a more recent development uses poly(ε-caprolactone) – instead of, e.g., partially hydrolyzed poly(vinyl acetate) or poly(vinyl alcohol) copolymers – in combination with starch. These blends are totally compostable and have a reduced thermomechanical stability.

4.3.4. Low-Molecular Carbohydrates – Sugars

Products containing both carbohydrate structures and oleochemical building blocks are mentioned in Section 4.3.1.

Mono- and disaccharides, as well as simple derivatives, are produced in consider-

able amounts. The world production of low-molecular carbohydrates in 1991 – 1992 (in 1000 t/a) is listed below [61]:

D-Sucrose	113 614
D-Glucose	5 000
D-Sorbitol	650
D-Lactose	180
D-Fructose	50
D-Gluconic acid	40
L-Sorbose	25
D-Isomaltulose	20
D-Mannitol	8
D-Maltose	3
Xylitol	3
D-Xylose	1
Dianhydrosorbitol	1

These products are used predominantly in the food sector. Worldwide more than 800 000 t of them go into the non-food area (1991 figures), that is, less than 1 % (EC: 153 000 t; Germany in the chemical industry sector ca. 29 000 t).

In the chemical industry these carbohydrates are used mainly in the pharmaceutical field, as building blocks in polyurethane raw materials (sugar polyethers), and to a considerable extent as a carbon source in biotechnological processes (e.g., for the production of citric acid). To some extent, waste materials, such as molasses and bagasse, are also important here (→ Sugar, Chap. 22.2.). Molasses is used to a large extent, e.g., as raw material for the production of citric acid via fermentation by *Aspergillus niger* [62]. The fermentation residues (vinasse), with only a low remaining sugar content, can be used in agriculture as a cattle feed additive or fertilizer, see, e.g., [63] (→ Sugar, Chap. 22.3.).

4.3.5. Other Renewable Resources

4.3.5.1. Polyisoprene

Natural rubber is described in detail in → Rubber, 2. Natural. Aside from natural rubber, which consists essentially of *cis*-1,4-polyisoprene, its *trans*-isomer, gutta percha, is also used industrially – however, to a considerably lower extent [64].

4.3.5.2. Natural Resins

Natural resins are described in → Resins, Natural. For the most important toxicological and legal aspects, see → Resins, Synthetic, Chap. 4. Although the economic importance of natural resins has declined, almost 1×10^6 t/a of rosin is still produced, chiefly in the United States and the People's Republic of China [65,66] (→ Resins, Natural, Chap. 5.6.).

Important applications are paint and varnish resins and printing inks.

4.3.5.3. Plant Polysaccharides ("Gums")

The polysaccharides that can be used with water for the production of highly viscous gels are grouped under the name gums (see, e.g., [67]).

Some of the most used gums in approximate order of their quantitative importance are guar gum from the seed of the guar plant (→ Polysaccharides); gum arabic (→ Polysaccharides, Chap. 7.), an acacia tree resin; locust bean gum (carob gum) (→ Polysaccharides) from the seed of the carob tree; alginates and carrageenans (→ Polysaccharides, Chap. 4., → Polysaccharides, Chap. 5.) from seaweed, etc.

Aside from their importance in the food industry as emulsifiers, stabilizers, thickeners, etc., gums have been widely used industrially: guar gum (a branched mannose – galactose polysaccharide) in mining, in the textile industry, and above all in the paper industry; gum arabic (alkali – alkaline-earth salts of complex branched polysaccharides) for writing inks, adhesives, and textiles; locust bean gum (branched galactomannan) for textile sizes and dyes, and for the paper industry. Alginates (essentially salts of polysaccharides from guluronic and mannuronic acid units) are used chiefly for foods, pharmaceuticals, dental molding compounds, etc.; and carrageenans (galactans partially esterified with sulfuric acid) are used essentially for foods [67].

4.3.5.4. Active Substances Based on Renewable Resources

The active substances based on renewable resources include the antibiotics produced by fermentation (→ Antibiotics). The most important fermentation raw material is sugar, at ca. 50 000 t/a (EC 1990).

Some vitamins form a second important group of pharmaceutical preparations for which renewable resources and their biotransformation play a part. The most important are Vitamin C (ascorbic acid, worldwide ca. 36 000 t from 60 000 t glucose or sorbitol), Vitamin B_2 (riboflavin, worldwide ca. 2000 t/a), and in considerably smaller amounts Vitamin B_{12}. An important raw material source, among others, is beet molasses.

Finally, very large amounts of L-glutamine (ca. 400 000 t/a worldwide, EU ca. 31 000 t/a) and L-lysine (ca. 40 000 t/a worldwide, EU ca. 10 000 t/a) are produced from agricultural raw materials for use in foods, pharmaceuticals, and feeds.

So-called natural product insecticides play a growing part in public debate. However, they were recommended and used early. Examples are nicotine (from tobacco leaves), pyrethrum (from chrysanthemum flowers), and other plant extracts, in some cases used for centuries (→ Insect Control, Chap. 3.).

However, unmodified natural substances cannot usually meet the criteria for modern plant protection agents – uniform and controllable action, toxicological acceptability, practicability, and economy. For example, the toxicity of nicotine to warm-blooded animals and the poor stability of pyrethrum make them unable to meet present-day standards. As a rule, therefore, ideas for the use of renewable resources for plant protection begin with modification of the natural model – example: pyrethroids.

The insect repellent azadirachtin occurring in the oil of the neem tree seed is attracting increasing interest. The oil has been used in India from time immemorial for insect control [68].

4.3.5.5. Flavors and Fragrances

Flavors and fragrances, such as those employed in foods, spices, drinks, medicine, toilet articles, cosmetics, and perfume, are often based on natural "renewable resources." In the Federal Republic of Germany, of the 40 000 t of flavors and fragrances produced in 1989 ca. one-third were of natural origin. Ca. two-third were produced synthetically, most of them to natureidentical substances. Fully synthetic aroma substances that do not correspond to natural products are the exception. Aroma substances of both animal and vegetable origin are employed, yet the products of animal origin, e.g., in perfumery (ambergris, musk, civet, etc.), are ever more costly and less used because of their increasing scarcity. A comprehensive survey is given in → Flavors and Fragrances.

4.4. Energy Use

The energy use of renewable resources comprises the use of biogas from industrial and agricultural wastes (e.g., for feeding into the public gas grid or for electricity generation); the cultivation of biomass for gasification, fermentation, or direct combustion; and the use of biofuels.

4.4.1. Biofuels

Biodiesel. The use of natural oils such as rapeseed oil or of rapeseed oil fatty acid methyl ester as a fuel for motor vehicles is increasingly discussed. While conventional diesel engines must be converted to use rapeseed oil, rapeseed oil methyl ester ("biodiesel"; produced from rapeseed oil by transesterification with methanol) is suitable directly for diesel engines. Although the ecological and economic evaluation of biodiesel is not yet complete [69, 70], a few aspects can be stressed:

In Germany alone, the area cultivated for rape is about 1×10^6 ha. Of this, up to now, only 42 000 ha (1991) has been used for the non-food area; yet by 1992, ca. 70 000 ha had been contracted for this purpose [70]. The potential is considered to be a maximum of ca. 400 000 ha [69]. Replacement of about 5 %, or in the medium term not more than 10 %, of diesel fuel is therefore achievable [70]. Environmental advantages then arise from the sulfur-free product and – even on allowing for emission of other greenhouse gases (N_2O, etc.) from the cultivation of the rape – from the reduction of CO_2 emissions due to the virtually closed carbon cycle. If 1 kg of diesel fuel is replaced by the required amount of 1.06 – 1.08 kg [70] rapeseed oil methyl ester, from 0.6 – 2.2 kg [69] to 2.3 – 2.8 kg [70] less CO_2 (including all other climatically active gases) is emitted. In addition savings in crude petroleum use per kilogram diesel fuel

of 0.76 – 0.91 kg [70] or 0.55 – 0.94 kg [69] occur.

Ethanol. Molasses as a waste material from cane sugar production is important for the production of ethanol as a motor vehicle fuel ("gasohol"). During fermentation, enormous amounts of slops are formed and must be coped with. An overall estimation of emission reductions as a result of ethanol addition is disputed [71, 72]; while the CO emissions are reduced, NO_x values in the exhaust gas increase [73]. Economically, the high production costs make this alternative fuel, even at only ca. 20 % addition, appear uncompetitive ("proalcool" program in Brazil) (→ Ethanol, → Automotive Fuels, Chap. 8.). For efforts in this regard in the United States, see, e.g., [74]. Bagasse (sugarcane residue) is either burned [e.g., for heating purposes (→ Sugar, Chap. 20.5.3.)] or used for the production of high-quality paper or cardboard. For a description of the extremely important fermentative ethanol synthesis, which clearly predominates over the synthesis from ethylene, see → Ethanol, Chap. 5.

4.4.2. Biogas

One possible means of waste utilization is the production of methane (biogas) from organic materials in sewage waters. This anaerobic enzymatic conversion (biomethanation) leads by oxidative and reductive processes to a mixture of ca. 60 mol % methane, ca. 40 vol % carbon dioxide, and small proportions of other gases. Biomethanation can also be carried out with " energy plants" as raw materials. The analogous conversion of organic landfill constituents likewise provides methane – CO_2 (landfill gas). A detailed description, including economic and ecological aspects, can be found in → Methane; → Gas Production, Chap. 1.1.4.

4.4.3. Heat from Biomass

Biomass firing in heating plants (e.g., with waste wood; whole-plant combustion of Miscanthus reeds, for example) plays an increasing role in projects and small decentralized plants [75]. Its profitability is not yet confirmed. However, of the energy sources bioethanol, biodiesel, and whole-plant combustion, the last has the smallest subsidy requirement at the present time [76].

4.5. Appraisal

4.5.1. Ecobalancing of Renewable Resources

Ecobalances seek to follow the life cycle of a product and to register the environmental influences associated with it [77]. Ecobalances in the field of production of renewable resources have already been drawn up [78, 79]. In the course of this, specific balancing problems occur with renewable resources compared to commercial processes. These concern especially the feedstock concept, the description of the emission situation, the land requirement and alternative land use, the dependence of the "production process" on conditions specific to the location (soil, weather, seasons), the description of alternative paths for waste use, and emissions into the soil.

4.5.2. Opportunities and Limits of Use of Renewable Resources

Renewable resoures have opportunities especially in those areas where the product of natural synthesis can be used directly or after simple processing and a lasting, economically advantageous supply of these raw materials is guaranteed. Conversely, renewable resources have their limits in fields of use where the aforementioned conditions are not met.

Thus, the use of renewable resources is reasonable when technical, economic, and ecological advantages over other materials exist.

1. Introduction

About 30 years ago, governments started to adopt measures to control chemicals with the aim of protecting people and the environment. Since then, rules and regulations have been introduced in many industrialized countries to assess and manage the risks of chemicals. It was recognized from the outset that harmonization of controls is important if the need for protection was to be reconciled with the aim of avoiding technical barriers to trade. The European Union (EU) took the first step in 1967 with the adoption of Directive 67/548 on classification, packaging, and labeling of dangerous substances, since then amended seven times to introduce appropriate risk assessment measures.

In the United States, the Toxic Substances Control Act (TSCA) became law in 1976. It introduced pre-manufacturing/pre-marketing assessment of the effects of chemicals.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.b08_181

In the 1970s, the OECD, grouping for 24 most industrialized countries in the world, launched a Chemicals Programme which is still the most important international initiative in the field of chemicals control.

All chemicals are toxic. The difference between them is the dose required to cause toxic effects: sugar and salt, if consumed by the kilogram, may be as lethal as milligrams of cyanide or strychnine. In addition to their toxicity, chemicals may be explosive, flammable, or corrosive. Others may have deleterious effects on our environment, e.g., chlorofluorocarbons.

Given that all chemicals are potentially dangerous, it is reasonable that precautions be taken to assess each chemical and to ensure that appropriate steps are taken to reduce the potential risks associated with its use to acceptable levels.

Control of chemicals includes the different steps illustrated in Figure 1.

Figure 1. Schematic of the process of chemicals control

In recent years, governments and industry have come to realize the part that consumer choice can play in protecting the environment from chemicals and other hazards. The need to develop more environmentally friendly products is now well recognized, and this article also deals with the objectives and function of ecolabeling systems.

2. Definitions

Risk assessment is a stepwise, iterative process, comprising the following steps:

1) Hazard identification: the identification of the adverse effects which a substance has an inherent capacity to cause
2) Dose (concentration) – response (effect) assessment: estimation of the relationship between the dose, or level of exposure to a substance, and the incidence and severity of its effect
3) Exposure assessment: determination of the emissions, pathways, and rates of movement of a substance, and its transformation or degradation in order to estimate the concentrations/doses to which human populations or environmental compartments are or may be exposed
4) Risk characterization: estimation of the incidence and severity of the adverse effects likely to occur in a human population or environmental compartment owing to the actual or predicted exposure to a substance
5) Risk estimation: quantification of the estimated likelihood in a risk characterization

3. Hazard Identification

The risk assessment of a chemical substance is a complex procedure based on comparison of its potential adverse effects with the reasonably foreseeable exposure of people and the environment to that substance. The identification of the potential adverse effects of a substance is the first step of this procedure [1].

Hazard identification is mainly based on a critical evaluation of the intrinsic properties of a substance, i.e., the physicochemical, toxicological, and ecotoxicological properties. For each of these groups of properties it is possible to define a number of specific end points, and for each of them internationally recognized guidelines [2], [3], to determine specific parameters. The interpretation of such parameters leads to the hazard identification of the chemicals.

3.1. Significance of Parameters

Intrinsic properties characterize the behavior of a chemical substance. They are directly linked to the structure of the molecule, although sweeping conclusions about behavior and properties

cannot be drawn simply because a substance belongs to a chemical class or family. It is enough to substitute one radical by another to induce specific properties which are not shared by the whole family.

Consequently, although the relationship between structure and activity is now an area of great scientific interest and ever-growing endeavors are being made to replace compulsory, costly, and long-term experimental studies by mathematical models, it is still necessary to use experimental methods to determine the basic properties from which the potential effects of a given substance can be deduced.

The following paragraphs deal with physicochemical, toxicological, and ecotoxicological properties, attempting briefly to clarify the significance of each of these and the principles underlying the methods of determining them, with direct reference to existing internationally recognized methods.

3.1.1. Physicochemical Properties

Physicochemical properties play an important role in the potential of a substance to produce adverse effects. There is a close correlation between physicochemical properties and the occurrence of toxic and environmental effects.

Each physicochemical property plays a specific role. For instance, the higher the molecular mass, the lower the possibility of absorption by the organism; the higher the melting point, the greater the physical stability of the substance; the lower the boiling point, the more readily the substance can be inhaled; liposoluble substances can penetrate more readily through the skin, facilitating their bioaccumulation, while hydrosoluble substances have a preference for gastric and pulmonary channels; substances able to lower surface tension are more readily absorbed and promote the absorption of substances which are difficult to absorb on their own. Similar considerations apply to the various sectors of the environment since substances can enter, move among, persist, and bioaccumulate in natural species.

Molecular Mass. The size of the molecule gives an idea of whether the substance is bioavailable, i.e., can be absorbed, assimilated, and metabolized by the organism. A comparatively small molecule can enter the organism and produce its effects much more readily than a large molecule. A high polymer cannot generally be absorbed and assimilated and is therefore much more inert as regards interaction with the human organism or other species.

Melting Point. The melting point characterizes the physical state of the substance at ambient temperature, and normal pressure. If the substance is solid at room temperature, it is less mobile than a substance in the liquid or gaseous state.

Boiling Point. Like the melting point, the boiling point characterizes the physical state of the substance under normal pressure conditions, providing important information on its ability to affect, for instance, channels of inhalatory exposure. In case of diffusion into the environment, it qualitatively indicates how easily the substance can be transferred into the air, and to what extent it diffuses into the environment. The higher the boiling point, the smaller the risk of inhalatory effects.

Relative density represents the mass ratio between a solid or liquid substance and water or, in the case of gaseous substances, between the substance and air.

When referred to water, it is normally expressed as d_4^{20} (mass of the substance measured at 20 °C and mass of water measured at 4 °C). If the substance does not dissolve in water, its density indicates whether the substance can be expected to stratify on the surface (density <1) or to sink to the bottom (density >1), which is important in relation to mobility in the environment and the diffusion of pollution into different compartments, including indirect human exposure.

When referred to air, substances which are denser than air (density >1) tend to stratify around the source of emission, constituting a major risk of exposure at relevant concentrations, while at density <1, diffusion into the air is easier, and the risk is generally reduced since it is less persistent in the vicinity of the emission site.

Vapor pressure is also an important way of finding out whether the substance, at ambient

temperature, may readily become volatile from a solution, another liquid, or solid matrix. It is defined as the pressure of saturation above a solid or a liquid. A substance with a high vapor pressure chiefly affects inhalatory and dermal channels of exposure. As regards diffusion into the environment, higher values are linked to an increased transfer potential. As regards physical danger, higher vapor pressure may be associated with risks of explosion and the need for greater precautions as regards storage, packaging, and transportation. In brief, greater risks are attached to high vapor pressure values.

Surface Tension. The ability of a substance to lower the surface tension of water is closely linked to its increased potential for absorption, permeation of barriers (membranes), and diffusion into water, even when the substance is scarcely hydrosoluble. A substance which can lower the surface tension of water may also make it easier for liposoluble substances which are insoluble or only slightly soluble in water to dissolve in water. A typical example is provided by surfactants which facilitate absorption of substances such as polycyclic aromatic hydrocarbons which are not hydrosoluble.

The surface tension value which is of interest is not that of the substance per se, but of its solution in water. The greatest risks are associated with low surface tension values measured in this solution.

Water solubility is defined as the concentration of saturation in water at a defined temperature. It is generally expressed as mass per unit volume of solution.

Hydrosolubility has direct implications as regards both potential toxicological and ecotoxicological effects. Hydrosolubility shapes adsorption by gastric or pulmonary channels, the possibility of dissolution in surface waters, and therefore the mobility in water and soil, as well as the precipitation of substances onto the soil in rain.

Fat solubility (liposolubility) expresses a substance's potential to dissolve and eventually accumulate in human and natural species' fats. The more liposoluble a substance, the more easily it can penetrate through the skin and produce local or systemic effects. It is normally measured using standard triglycerides with defined fatty acids content. Alternatively, the solubility in organic (possibly nonpolar) solvents may be useful information.

Partition Coefficient *n*-Octanol/Water. The problem of bioaccumulation may reach very high proportions in natural species. Aquatic species, which filter enormous quantities of water, accumulate liposoluble substances on a scale which increases with the species' physical size and life expectancy, playing a part in "magnifying" pollution of the trophic chain.

An idea of the bioaccumulation capacity of a substance may be gained from the *n*-octanol/water partition coefficient. This is obtained by establishing the ratio at which a given substance is distributed when brought into contact with a system of two immiscible phases formed by normal octyl alcohol (*n*-octanol) and water. The *n*-octanol simulates the fatty phase: if the substance dissolves to a greater extent in the aqueous phase the partition coefficient assumes negative values (it is normally expressed as a decimal logarithm, $\log P_{ow}$), showing that the substance is more hydrosoluble than liposoluble; positive values in the case of substances which dissolve to a greater extent in the octanol phase, indicating that the substance can bioaccumulate (normally this requires $\log P_{ow} > 3$).

The partition coefficient is particularly important for substances which are scarcely soluble in water and fats. It might be thought that low liposolubility entails a low level of risk of bioaccumulation, whereas if the substance is more liposoluble than hydrosoluble (i.e., high partition coefficient), bioaccumulation may also occur, but to a lower extent because of the low absolute liposolubility. The partition coefficient is independent of the absolute values for liposolubility and hydrosolubility, expressing the ratio between them.

Flammability. This property, like the following physicochemical properties, provides direct information on the possibility of a so-called physical effect (it is better to talk of physicochemical effects, since oxidation is a typical chemical effect). While the previously described properties "characterize" the substance, giving indirect information on the potential bioavailability and mobility into the environment, the

properties regarding physical effects provide information on immediate and direct risks. Most damaging accidents are linked to physical effects, often with consequences which are disastrous in terms of their size, persistent effects, and number of casualties.

The risk of flammability may derive from a low vapor ignition temperature in the presence of an ignition source (primer) or from the possibility of the substance igniting spontaneously in air with no ignition point (autoflammability).

For liquid products, the flash point is the parameter which allows quantification of the flammability risk. It is defined as the lowest temperature, at a corrected pressure of 101.325 kPa, at which a liquid emits vapors in such quantity as to produce a flammable vapor/air mixture. Experimentally, the substance is slowly and progressively heated and, at regular intervals, its vapors are exposed to a spark: the lowest temperature at which the vapors/air mixture flashes is the flash point. This type of test is appropriate for liquids and low-melting-point substances. A different type of test is carried out for solid substances, yielding a simple positive/negative response, by evaluating the substance against a reference flammable product.

If the substance decomposes during heating, the flash point is still of interest, as the ignition of the vapors may be due to the mixture of decomposition product vapors rather than the substance per se. Moreover, account has to be taken of the case in which the substance per se is not flammable, but releases flammable gases in contact with other substances, e.g., water.

Some gaseous substances ignite in the presence of a primer at low or very low temperature; in this case it is useful to know the range of concentration in air at which flame propagation occurs.

Information on autoflammability can prevent serious accidents, especially during long-term storage of chemical products. It is vital to know whether a substance may autoignite at temperatures which are foreseeable under bad storage conditions.

Explosive Properties. A substance is considered to have explosive properties if, following heating, shock, or friction, it may decompose abruptly, releasing large quantities of energy and/or gas. Explosive properties are tested by methods which take account of the three different possibilities (heat, shock, friction). If the substance is shown to have explosive properties similar to or greater than those of a reference substance (e.g., dinitrobenzene) it is considered explosive.

Oxidizing Properties. A substance with oxidizing properties may, when brought into contact with chemically oxidizable organic or inorganic substances, bring about dangerous reactions causing fire, explosion, or the formation of other hazardous substances. Oxidizing properties are not just related to the presence of oxygen in the molecular structure, but to its potential for acting more generally as an oxidant in an oxidation – reduction reaction. In many cases, specific tests are not necessary to determine whether or not it is oxidizing; examination of its structural formula may provide predictive information. Organic peroxides, for instance, are generally considered as oxidizing, even in the absence of test results. The only doubt is whether they should also be considered as explosive; for this, experimental evidence is needed.

3.1.2. Toxicological Properties

Toxicological properties are of direct interest in assessing the risk of chemical substances. They include a range of effects understood either as general poisoning of the organism or aimed at one or more particular target organs, and whose intensity is generally proportional to the dosage absorbed and to specific effects, which may be independent of dose, e.g., mutagenic and carcinogenic effects. There may also be immediate effects, generally acute, or effects deferred in time, linked to the intake of small, continued doses, or with a period of latency before the effects appear.

The dosage administered and the duration of toxicological tests are inversely proportional with reference to acute, subacute, subchronic, and chronic studies. When studying acute effects, the substance is usually administered to test animals as a single dose, at a level sufficiently high to cause death. When studying subacute effects, lower dosages are used, but for a longer and continuous period (28 d). For subchronic toxicity, even smaller dosages are used,

but over a period corresponding to ca. 10 % of the animal's life; for chronic toxicity the test is extended throughout the animal's life, usually at even lower dosages.

Some basic properties need to be differentiated for assessment of the various types of risk connected with toxicological properties.

Acute toxicity includes those effects which are or may be produced following a single administration. In terms of acute effects, it is common to distinguish between systemic effects (lethal effects following oral, cutaneous, or inhalatory administration) and local effects, such as irritation of the eyes and skin, or corrosive and sensitizing properties.

Each of these effects needs to be examined in slightly more detail.

LD_{50} and LC_{50}. The acute lethal effects are generally evaluated through the LD_{50} (dose killing 50 % of animals tested), valid for oral and cutaneous administration, and the LC_{50} (concentration killing 50 % of animals tested), valid for inhalatory administration. Other routes of administration, e.g., peritoneal, intramuscular, or intravenous, although of some interest, have no direct correlation with the study of chemical substances in relation to personal, domestic, professional, or environmental exposure of humans.

A basic consideration underlies the determination of the oral LD_{50}, cutaneous LD_{50}, and inhalatory LC_{50}: the greater the toxicity of the substance, the smaller the value obtained.

The oral LD_{50} is generally determined by administering a known quantity of the substance to the animal (the rat is taken as a reference) by gastric probe (gavage), possibly dispersed in an appropriate vehicle, depending on the solubility of the substance in water or oil, or a different inert vehicle for insoluble substances. After administration, the animal must be observed for up to 14 d. The LD_{50} is assumed to be the dosage, expressed in milligrams substance per kilogram animal body weight (mg/kg), able to cause, during the observation period, death of 50 % of the test animals. In order to determine the LD_{50}, it is necessary, after preliminary tests, to use groups of animals to which a range of increasing dosages are administered, so that the LD_{50} value may be interpolated. The test should not be limited to establishing the number of animals killed in relation to those tested, but should also be used to show, through appropriate histopathological studies, the organs chiefly affected, and thereby to gather information on the possible mechanism of action of the substance.

The cutaneous LD_{50} is determined by applying the substance, possibly dissolved or dispersed in an inert vehicle, to the shaved skin of the test animal (rat or rabbit) and ensuring that it remains in contact for a period of time (24 h or periods depending on the substance's potential corrosive or irritant effects). As mentioned above, liposoluble substances can readily penetrate through the skin, but this possibility is not significant for nonliposoluble substances. Observation must be continued for 14 d after the removal of the bandage, and subsequent investigations should endeavor to gather any other useful information. The cutaneous LD_{50} is also expressed in mg/kg.

The inhalatory LC_{50} is determined by exposing the animal (rat) for 4 h to an atmosphere in which the substance is uniformly dispersed at a constant concentration. The dosage capable of killing 50 % of the animals is expressed as a concentration, in milligrams per liter of air.

For some substances in the form of dusts, it may be difficult or impossible to disperse a concentration of the substance sufficient to cause fatal effects. In such cases, it is possible only to indicate that the LC_{50} is higher than the maximum concentration tested.

Irritant or Corrosive Properties. The irritant or corrosive properties of a test substance are determined with respect to the skin and the eyes. Two separate tests are conducted on rabbits and provide qualitative or semiquantitative information.

Irritant or corrosive effects on the skin are tested by leaving the substance in contact with the intact, shaved skin of the animal, and observing the effects produced after 4 h; these effects may range from the absence of effects to erythema, the formation of eschar or edema, or tissue corrosion. Corrosion occurs when the whole thickness of cutaneous tissue is destroyed.

Irritant effects on the eyes are tested by instilling a small quantity of the substance into one of the animal's eyes and using the other eye as a reference. The severity of the effects is compared with a reference scale, looking in particular at the effects on the cornea, iris, and conjunctivae.

Sensitizing Properties. Sensitization is an allergic cutaneous or inhalatory reaction occurring when the organism, hypersensitive to a chemical substance, is exposed to the substance, even at very low concentrations. This property may be experimentally evaluated only for skin sensitization; no methods exist for the evaluation on test animals of inhalatory sensitization. The test substance is administered to the animal (guinea pig) by cutaneous injection (induction phase) and after an appropriate period the administration is repeated (challenge phase), observing whether the animal is subject to sensitization phenomena.

Sensitizing effects on the respiratory tract are considered a more severe hazard. However, given the lack of a practicable test, a substance is considered to be sensitizing by inhalation on the basis of epidemiological evidence.

Subacute, Subchronic, and Chronic Toxicity. Medium- or long-term toxicity tests provide essential additional information on the more hidden effects which the substance may cause by exposure to low dosages over a period of time. This type of test can also be conducted via the various routes of exposure (oral, inhalatory, cutaneous) in accord with the main route of human exposure.

A basic aim of these tests is to identify the maximum dose level at which the substance does not present toxic effects. This makes it necessary to test several increasing dose levels, so as to determine the dosage at which toxic effects start to appear. This makes it possible to show whether the toxic phenomenon is dose dependent, i.e., whether the intensity of the effect is proportional to the dose administered.

Tests results in the literature contain a range of notation:

1) NEL (no effect level), expressing the maximum level where there are not even minor effects
2) NOEL (no observed effect level), expressing the maximum level at which no effects have been observed
3) NOAEL (no observed adverse effect level), expressing the maximum level at which no adverse effects have been observed

Between NEL and NOEL, generally the latter is preferred, expressing the actual experimental dose level at which no effects have been observed; NEL is a more theoretical value, situated somewhere above the NOEL, more precisely between the dose level corresponding to the NOEL and the subsequent dose level. For identification of the NOAEL, the problem is to characterize exactly what "adverse effect" means. There is the need to distinguish between severe and minor effects, and the debate is still open, although the internationally recognized guidelines have attempted to define, at least in general terms, an adverse effect.

In any case, the NOEL (or NEL, or NOAEL) should be expressed in milligrams substance per kilogram animal body weight and day ($mg\,kg^{-1}\,d^{-1}$).

If the test is conducted by administering the substance to the animal in its food, the results may also be expressed as ppm in the diet (mg/kg of food). It is possible to convert, within an acceptable approximation, one value to another. In the rat, for instance, this conversion consists of dividing the concentration of the substance in the food by 20. Animals other than the rat, with metabolism closer in some ways to that of humans, are mice, dogs, and monkeys.

Subacute toxicity tests are designed to reproduce repeated exposure over short periods. Subchronic toxicity tests may, in some cases, replace chronic toxicity tests; if subchronic toxicity tests, which last 3 months in the case of rats (i.e., 10 % of their life expectancy), do not reveal major effects at sufficiently high dosages and it is assumed that the chronic toxicity tests are not likely to add relevant information, longer term tests may not be necessary, thereby reducing suffering of the animals and study commitments. Chronic toxicity tests are conducted for the animal's entire life and are designed to reproduce continuous, prolonged exposure.

Various macroscopic (body weight, general condition, food intake) and chemical and clinical measurements (blood, urine, and other specific tests) are also conducted during the main test. Small groups of animals may be killed at predetermined times for histopathological studies which are in any case carried out at the end of the trial with a detailed examination of the individual organs and glands.

The NOEL value is a basic factor in assessing the risks connected with the toxicity of a given substance as a result of medium- or long-term

exposure. The smaller the NOEL value, the more hazardous the substance, with the result that the risks are inversely proportional to the numerical value of this parameter.

Mutagenesis. A substance is considered mutagenic if its adsorption may produce heritable genetic damage or increase their frequency. Assessing a substance's ability to cause mutation in humans, at germinal or somatic level, is very difficult on the basis of current knowledge. Several in vivo and in vitro tests are designed to predict the presence of a potential ability to cause mutations. The comparative simplicity and brevity of these tests, together with the knowledge that many carcinogenic substances are also mutagenic, has promoted increasing interest in a wide-ranging set of mutagenesis tests, each of which can provide specific information on mutagenic potential, bearing in mind that general conclusions cannot be drawn from a single test. It is therefore necessary to carry out a battery of tests to obtain a minimum set of information.

In vivo tests obviously have a greater significance than in vitro tests, although the latter are more sensitive. In vivo studies are usually performed only when a battery of in vitro tests gives positive results.

A number of categories for mutagenic substances have been established for operating purposes and for risk assessment. The EU and other international and national organizations have formulated criteria defining different categories of danger with different levels of mutagenic potential. The allocation of a substance to one or other of these categories provides an overall qualitative assessment of its possible mutagenic potential.

The EU, for instance, has adopted the following classification:

Category 1: substances known to be mutagenic to humans. There is sufficient evidence to establish a causal association between human exposure to a substance and heritable genetic damage.

Category 2: substances which should be regarded as mutagenic to humans. There is sufficient evidence to provide a strong presumption that human exposure to the substance may result in the development of heritable genetic damage, generally on the basis of appropriate animal studies or other relevant information.

Category 3: substances which cause concern, owing to possible mutagenic effects, but in respect of which the available information does not satisfactorily demonstrate heritable genetic damage. There is evidence from mutagenicity studies, but this is insufficient to place the substance in Category 2.

As in the case of other properties of chemical substances, it is possible in mutagenesis to use the structure – activity relationship for an initial assessment of possible mutagenic effects. Extremely reactive substances which are free radical donors are likely to give positive results in mutagenesis tests.

Carcinogenesis. Substances are considered carcinogenic if, after exposure (generally long-term) by inhalation, ingestion, or skin contact, they may produce cancer or increase its frequency. Test protocols have been drawn up at international level for studies of carcinogenic potential of chemical substances.

These long-term tests, conducted using the exposure routes (oral, inhalatory, cutaneous) assumed to be most representative of normal exposure conditions for humans, include detailed histopathological investigations intended to show the number, type, and location of tumors; data need to be statistically processed in comparison with control groups to take account of the natural occurrence of tumors in the particular strain of animals studied, and to establish significance.

Several, substantially similar, international classifications have also been formulated for carcinogens; substances are allocated to different categories in relation to the carcinogenic potential demonstrated.

The following three categories, in decreasing order of risk, have been formulated by the EU:

Category 1: substances known to be carcinogenic to humans. There is sufficient evidence to establish a causal association between human exposure to a substance and the development of cancer.

Category 2: substances which should be regarded as carcinogenic to humans. There is sufficient evidence to provide a strong presumption that human exposure to a substance

may result in the development of cancer, generally on the basis of appropriate long-term animal studies or other relevant information.
Category 3: substances which cause concern owing to possible carcinogenic effects, but in respect of which the available information is not adequate for satisfactory assessment. There is some evidence from animal studies, but this is insufficient to place the substance in Category 2.

Also in the case of carcinogenesis, the fact that a substance belongs to a chemical family whose carcinogenic properties are known should pave the way for detailed specific studies.

Embryotoxicity. Teratogenic effects, i.e., nonheritable birth defects, produced by a chemical substance, are now covered by a broader class of effects, covering all possible effects on reproduction; embryotoxicity seems to be the most appropriate term. Two main subcategories of effects exist: possible effects on human fertility, and developmental toxicity.

Substances are considered dangerous to human fertility if they may produce or increase the frequency of damage either to reproductive functionality or to the reproductive capacity of males and females. Substances are considered toxic to development if they may produce adverse nonheritable effects in the offspring, or increase their frequency. There are also specific test protocols to predict potential embryotoxicity on the basis of animal studies.

The present EU scheme distinguishes three categories for each kind of effect:

1) Substances dangerous to human fertility
   Category 1: substances known to impair fertility in humans. There is sufficient evidence to establish a causal relationship between human exposure and impaired fertility.
   Category 2: substances which should be regarded as impairing fertility in humans. There is sufficient evidence to provide a strong presumption that human exposure may result in impaired fertility on the basis of appropriate animal studies or other relevant information.
   Category 3: substances which may cause concern for human fertility, essentially on the basis of animal studies providing sufficient evidence to cause a strong suspicion of impaired fertility in the absence of toxic effects.
2) Substances dangerous to human development
   Category 1: substances known to cause developmental toxicity in humans. There is sufficient evidence to establish a causal relationship between human exposure and subsequent developmental toxic effects in the progeny.
   Category 2: substances which should be regarded as causing developmental toxicity to humans. There is sufficient evidence to provide a strong presumption that human exposure to the substance may result in developmental toxicity, generally on the basis of animal studies or other relevant information.
   Category 3: substances which cause concern owing to possible developmental toxic effects, generally on the basis of animal studies which provide sufficient evidence to cause a strong suspicion of developmental toxicity in the absence of signs of marked maternal toxicity.

3.1.3. Ecotoxicological Properties

As toxicological properties, studied by tests on animals, are indicators of potential effects in humans, so ecotoxicological properties, studied through tests on natural species, are indicators of the potential effects which a substance may have on the environment. Some species, considered to be "biological indicators" are taken to be representative of the various compartments (water, soil, air).

It is difficult to make a clear distinction between these compartments since air, soil, and water interact. Soil contamination can be assessed directly through toxicity tests on species which live in the soil, e.g., plants and earthworms, but soil may be permeated by water and washed by atmospheric and surface waters. This leads to contamination of the water compartment and aquatic species, both in situ and in watercourses and catchment areas. Diffusion of a substance in the air may lead to precipitation and dissolution in water. Diffusion in the soil or in water

may lead to volatilization and thus to contamination of the air. Direct contamination of rivers or lakes may pave the way for diffusion through the soil. Contamination of soil may contaminate land species (flora and fauna) which may become the prey of birds.

The aim of these tests is to identify sufficiently representative biological indicators of the toxicity of a substance to ecosystems.

Toxicity in Fish. Toxic effects on fish may occur following acute or prolonged exposure to concentrations which may be very low, bearing in mind the ability of aquatic organisms to recycle very high quantities of water and, in many cases, to bioaccumulate toxic substances.

Acute toxicity is evaluated by keeping the fish for 48 – 96 h in water containing a known concentration of the substance. A number of tests have to be conducted in parallel to determine the concentration at which no lethal effect occurs (LC_0), the concentration which is fatal for all tested animals (LC_{100}) and the median concentration which is fatal for 50 % (LC_{50}). The latter is normally calculated by interpolation among the other data or at least between the two extreme values. LC_{50} is expressed in milligrams per liter of water (mg/L).

The smaller the LC_{50} value, the greater the toxicity of the substance for the species tested.

Long-term toxicity in fish is of interest, even if their sensitivity to extraneous substances in water is very high, and the LC_{50} can be taken as a very representative parameter. The LC_{50} and the LC_{100} are often very close numerically. It is important to look for long-term toxicity in substances which are not highly hydrosoluble since ingestion of very small quantities of substances in the aqueous medium may present delayed toxic effects.

The species recommended for the test are:

Brachydanio rerio (zebra fish)
Pimephales promelas (fathead minnow)
Cyprinus carpio (common carp)
Oryzias latipes (red killifish)
Poecilia reticulata (guppy)
Lepomis macrochirus (bluegill)
Salmo gairdneri (rainbow trout)
Leuciscus idus (golden orfe)

On the basis of tests specifically designed to measure long-term toxicity, it is possible to identify an NOEC (no observed effect concentration).

Toxicity in Daphnia. *Daphnia* is a very small crustacean that makes rapid and frequent swimming movements. The *Daphnia* test is designed to detect the immobilization effect, which is taken as an index of the adverse effects caused by the substance.

The substance is dissolved in water, over a range of increasing concentration and the *Daphniae* are exposed for 48 h. The mean effective concentration (EC_{50}) is generally interpolated between the EC_0 and EC_{100}. All data are expressed in mg/L.

As for fish, the lower the EC_{50} value, the greater the acute toxicity of the substance for *Daphnia.* There may be problems with substances which are scarcely hydrosoluble in acute toxicity tests with *Daphnia.*

Effects on reproduction may be evaluated through long-term tests (21 d) on *Daphnia magna*. An NOEC can be identified.

Acute Toxicity in Birds. No acute toxicity tests for birds formulated at international level are yet available, but the literature provides toxicity data for a number of species (quails, ducks, pigeons, chickens).

Administration generally takes place orally through the diet, linking the quantity ingested with body weight. Use is therefore made of the dose level which is lethal for 50 % of the birds in the test (LD_{50}), expressed in mg/kg.

Toxicity in Higher Plants. Plants are biological indicators of major importance. The damage to higher plants by environmental pollution, for instance, is commonly measured. Up to now there have not been any standard methods, given the wide range of species and reactions which may be obtained. The tests available are based on the effect which a given substance may have on the germination and growth of the plants tested, expressed as the EC_{50}.

Herbicides, which by their nature and function, have toxic effects on plants (phytotoxic effects) may be considered as reference substances. In the absence of accepted international methods, the substance can only be generally considered as phytotoxic, moderately phytotoxic, or nonphytotoxic.

Toxicity in Earthworms. The earthworm is an important indicator of soil life following contamination by chemical substances. This information, together with data from toxicity tests on plants, relates therefore to the soil compartment.

The test already defined at international level uses *Eisenia foetida* kept in standard artificial loam soil treated with different concentrations of the substance. After 14 d the soil is examined and the surviving earthworms counted. The result is expressed as LC_{50} with respect to the soil.

Effects on Algae. Algae are important biological indicators. Unfortunately, the available data focus largely on the detection of effects inhibiting algal gowth, while experience has shown that major adverse effects on the environment may result from the abnormal increase of algae as a result of contaminants in the water.

The tests are carried out in water and the EC_{50} is understood as the concentration which inhibits growth by 50 % (also referred to as inhibitory concentration, IC_{50}). It is more convenient to refer to the substance's ability to produce both positive and negative effects, i.e., changes in normal development.

Persistence. The lifetime of a chemical substance may vary as a function of external conditions. A substance which is kept dry in a dark, sterile, oxygen-free atmosphere can remain unchanged indefinitely.

Once introduced in the environment, a substance is subject to different kinds of aggression which, depending on the molecular structure, may produce total or partial degradation of the substance. Such aggression may be divided in two types: biotic and abiotic.

The more rapidly decomposition takes place, biotically or abiotically, the lower the chance of the substance having any residual adverse effect. Nevertheless, unless the substance is totally decomposed to simple compounds (H_2O, CO_2, NO_x, SO_x, PO_x), identification of the degradation products is essential for complete evaluation of residual effects; the degradation products may be more dangerous than the parent molecule.

Biotic degradation is caused by bacteria and microorganisms which use the substance for their own development, causing it to decompose. Organic chemicals are largely formed from carbon and other elements such as hydrogen, oxygen, nitrogen, sulfur, and phosphorus, and they may become involved in the various cycles of use and conversion by bacteria and microorganisms.

The methods formulated for the determination of biodegradation are therefore based largely on determining the quantity of oxygen needed for the oxidation, in due time, of the organic carbon contained in the test substance. Bearing in mind the various environmental conditions in which the substance may be dispersed, the analytical methods set out different conditions for the addition of bacterial inocula, e.g., in activated sludge and sewage, and different operating methods which attempt to ascertain whether the substance can be decomposed under particular conditions by the action of bacteria and microorganisms.

An initial measurement (ready biodegradability) is based on determining the percentage of the substance degrading over 28 d; a substance which degrades by more than 70 % is generally considered biodegradable.

The biochemical oxygen demand (BOD) is related to the chemical oxygen demand (COD), the latter representing the amount of oxygen needed for complete oxidation of the substance by chemical methods. The BOD/COD ratio is a useful factor for assessing to what extent the substance degrades by biotic media.

Abiotic Degradation. The degradation of a chemical substance may also take place abiotically as a result of hydrolysis if it comes in contact with water or moisture and/or as a result of exposure to sunlight (photodegradation).

Decomposition by hydrolysis is usually assessed by determining the concentration of the substance in an aqueous solution as a function of time and pH, to simulate a range of possible acid or basic conditions in the receptor medium. The "half-time" $t_{1/2}$ is calculated as the time for the concentration of the substance to reduce to half the initial concentration.

Photodegradation is ascertained by exposing the substance to light of a given wavelength, under specific environmental conditions, and determining the residual fraction as a function of time. Here too, the aim of the test is the evaluation of $t_{1/2}$.

3.2. Interaction of Parameters

Each of the parameters examined in Section 3.1 gives information on the risk potential for humans and the environment of a chemical substance. Such parameters are, however, not completely independent. Some physicochemical properties, besides being clear indicators of mobility in the various environmental sectors, directly influence the biological behavior.

3.2.1. Hydrosolubility

Hydrosolubility is an important predictor of the behavior of a chemical substance, both in terms of mobility and biological activity. A substance with high hydrosolubility behaves in a largely predictable manner with respect to possible effects on human health and the environment.

A first consequence of high hydrosolubility is, in general, reduced liposolubility; there is almost always a predominance of either lipophilic or hydrophilic groups in a molecule. Only in some types of chemicals (e.g., surfactants) are both types of group represented to such an extent that the substance has hydrosolubility very similar to its liposolubility. Another direct influence is its *n*-octanol/water distribution coefficient log P_{ow}; since high hydrosolubility often corresponds to a low liposolubility, log P_{ow} is negative, resulting in a slight bioaccumulation potential in living organisms.

From the point of view of possible direct effects on humans, a hydrosoluble substance is easily absorbed through the gastrointestinal tract or the pulmonary alveolae; but it is less likely to be absorbed through the skin. In toxicological studies on animal species, it is necessary to concentrate on the oral route and, depending on the volatility (liquids) or particle size (solids), on inhalation. In the initial analysis, the cutaneous route can be ignored for possible systemic effects, though it remains relevant for possible local (corrosive/irritant) effects.

From the environmental aspect, hydrosolubility is fundamental in evaluating possible effects on aquatic species. Experiments on biological indicators such as fish, *Daphnia*, and algae are useless unless the substance has significant hydrosolubility. The same also applies to biotic and abiotic degradation rates.

3.2.2. Liposolubility

As hydrosolubility and liposolubility are generally inversely proportional, it may be expected that a substance with a high liposolubility will behave in a complementary manner to a substance with a high hydrosolubility.

A substance with high liposolubility generally has a low hydrosolubility and a high octanol/water distribution coefficient, with a significant bioaccumulation potential. From the point of view of the effects on humans, the cutaneous route becomes important as a liposoluble substance can readily be absorbed through the skin to produce immediate or subsequent systemic effects, the latter of which are particularly important because of the potential for bioaccumulation.

It is often difficult to evaluate the potential environmental danger of liposoluble substances since, at least as regards aquatic behavior, the tests are performed in aqueous solution without the addition of auxiliary solvents which can affect the hydrosolubility of the substance. Important is the real concentration, not the nominal concentration (this refers to the amount of substance added to the aqueous medium, and it may not be completely dissolved). If the hydrosolubility is negligible, acute toxicity studies in fish, *Daphnia*, and algae are irrelevant. It is wrong to believe that a highly liposoluble substance does not constitute a risk to the aquatic environment; incidents connected with the accidental discharge of petroleum products (crude oil in particular) reinforce this point. On the other hand, the presence of extremely low concentrations in water may constitute a danger for aquatic species, given their bioaccumulation capacity.

3.2.3. Corrosion/Irritation and Oxidizing Power

Chemically aggressive substances such as oxidizing agents can produce local effects on the skin. High reactivity is often synonymous with low persistence; it is particularly important to investigate the acute effects. It seems certain that chemically aggressive substances can influence genotoxicity.

Corrosive substances can present problems in interpretation of results, if they are tested to evaluate possible systemic effects. If a substance produces local effects, this does not mean that it cannot also produce systemic effects. It is precisely through the local effect that the cutaneous barrier is weakened, and the substance can enter the circulation and produce effects on organs or systems remote from the entry site. In spite of this, in order to understand the exact mechanism of action, it is important to distinguish mortality due to the local effect (e.g., perforation of the esophageal tract due to the corrosive effect) from mortality due to the systemic effect.

3.3. Classification Schemes: The European Union System

A chemical substance is characterized by a critical examination of its physicochemical, toxicological, and ecotoxicological properties. However, it is not feasible to require that every time a chemical substance (per se, or mixed with other substances) is handled, transported, or stored, it should be subjected to a comprehensive evaluation. Those who may come into contact with a chemical substance, whether laboratory staff or domestic users, hardly ever have sufficient knowledge to make such an evaluation; this work is therefore entrusted to committees of experts who systematically examine the relevant data in order to draw up concise guidelines. It is vitally important that such guidelines be expressed in clear and understandable terms, so as to provide essential information not only on the risk potential of the substance, but above all on the measures to minimize such risks.

Such ideas are implemented in practice via the danger classification in conjunction with the danger guidelines and information on reducing risk, generally using one or more danger symbols accompanied by standard wording describing, very clearly and in terms comprehensible to all, the risk associated with a possible use of the chemical substance, and the measures to be adopted to prevent exposure and reduce the consequences of accidents.

These classification systems generally tend to cover all possible effects of a substance, and are intended to inform users directly through the labeling. More specialized types of classification exist, aimed at specific end points, e.g., carcinogenesis; these classifications are drawn up by national or international agencies, (e.g., EPA, IARC) and are regularly updated, with the aim of protecting human health, particularly that of exposed workers.

Besides these "specific" classifications, there are the far more widely used "generic" classifications. The two systems that are most widely used are:

1) The UN classification system for the transport of dangerous goods
2) The EU classification system for the introduction of dangerous substances onto the market

3.3.1. Transportation

National or international transport of goods can be by air, rail, road, sea, or inland waterways. For each of these modes of transport, standards authorities have issued international norms regulating the technical details of the transport of dangerous goods. The term "goods" is extremely general, but covers both substances and dangerous preparations. Such norms (e.g., RID for rail transport, ADR for road transport) differ from one another as regards the packaging characteristics and the safety measures to be adopted, because the particular features of each type of transport have to be taken into account. However, as regards the criteria for classifying goods, they all follow the system defined by the UN and published in the "Orange Book" [4].

The Orange Book not only sets out classification criteria for transport, but for each class lists and regularly updates the products officially recognized as belonging to the class; such lists are not exhaustive, but they are supplemented by guideline criteria which increase their scope. Such guideline criteria cover a total of nine danger classes, these are treated in detail in →Transport, Handling, and Storage, Chap. 3.

Each of the nine classes is characterized by a specific danger symbol, applied to the external packaging of the dangerous product being transported (Table 1). The general criteria are then defined in more detail according to the technical demands of each type of transport.

Table 1. Danger symbols for transport of dangerous goods

Class 1

Explosives
Symbol (exploding bomb): black
background: orange

Class 1—*Division 1.4*
(*Except safety explosives*)

Class 1—*Division 1.5*

Explosives
Background: orange; figures: black; numerals must be ca. 30 mm in height and ca. 5 mm wide (for a label measuring 10 × 10 cm)

Class 2

Compressed Nonflammable Gases
Included in Class 2
Symbol (gas cylinder): black; background: green

Class 3

Flammable Liquids
Symbol (flame): black;
background: red

Class 4—*Division 4.1*

Flammable Solids
Symbol (flame): black;
background: white with vertical red stripes

Class 4—*Division 4.2*

Substances Liable to Spontaneous Combustion
Symbol (flame): black;
background: upper half white, lower half red

Class 4—*Division 4.3*

Substances which, in Contact with Water, emit Flammable Gases
Symbol (flame): black;
background: blue

Class 5

Oxidizing Substances; Organic Peroxides
Symbol (flame over circle): black;
background: yellow

Class 6—*Division 6.1*

Poisonous (toxic) Substances
Danger groups: I and II
Symbol (skull and cross-bones): black; background: white

Class 6—*Division 6.1*

Poisonous (toxic) Substances
Danger group: III
The bottom part of the label should bear the inscription:
Harmful stow away from foodstuffs
Symbol (St. Andrew's cross over an ear of wheat): black;
background: white

Class 6—*Division 6.2*

Danger Infectious Substances
The bottom part of the label should bear: INFECTIOUS SUBSTANCE (Optional) and the inscription: **In case of damage or leakage immediately notify public health authority** (optional)
Symbol (three crescents superimposed on a circle) and inscription: black;
background: white

Table 1. (Continued)

Class 7

Radioactive Substances
(a) Category "white"; background: white with one vertical red stripe in the bottom half. Text (mandatory) black in bottom half of label: **Principal radioactive content . . . Activity of contents . . . curies . . .**
Symbol (trefoil): black

Radioactive Substances
(b) Category "yellow"; background: top half yellow, with two or three red stripes in the bottom half white. Text (mandatory) black in bottom half of label: **Principal radioactive content . . . Activity of contents . . . curies . . . Transport index . . .**
Symbol (trefoil): black

Class 8

Corrosives
Symbol (acids spilling from two glass vessels and attacking a hand and a metal): black; background: upper half white, lower half black with white border

The importance of the transport classification is also due to the fact that, in some countries, it is the only classification system and is therefore used, apart from the specific field of transport, as a generic characterization method.

3.3.2. The EU Classification for the Marketing of Dangerous Substances

In the European Union, a system of classification has been developed since the 1970s, covering the labeling to be applied when dangerous substances and preparations are marketed; this includes both professional and domestic use. In the EU, classification norms and labeling for transport are carefully distinguished from those relating to commercial use; e.g., a container or crate intended for transporting tins of paint is labeled according to the norms for transport, whereas the tins of paint are labeled according to the norms for commercial use.

Only in cases involving a common single form of packaging, which is used for both transport and marketing, is it permitted to use a mixed label, consisting of the danger symbol specified by the transport norm and the danger wording and safety instruction wording specified by the marketing norm. EEC Directive 67/548 [5] presents the Community's legal basis for the whole range of norms issued for classification and labeling of dangerous substances and preparations. A group of experts from the Member States is engaged in classifying substances considered to be a priority at the community level; ca. 1500 substances have been officially classified, as reported in Commission Directive 93/73 [6]. Since the basic directive, in an updated version [7], also provides that substances not officially classified should be evaluated by the manufacturer or importer for the purposes of possible classification and labeling (regarded as provisional), the Community system has to clarify the criteria for danger classification in order to provide industry with a clear, unambiguous framework that avoids as far as possible subjective evaluation and differing interpretation of the data. The most up-to-date version (1998) is Commission Directive 98/98/EG [8]. Application of these criteria enables substances to be

allocated to one or more of the following danger categories:

Explosive
Extremely flammable
Readily flammable
Flammable
Oxidizing
Very toxic
Toxic
Harmful
Corrosive
Irritant
Sensitizing
Carcinogenic
Mutagenic
Toxic to reproduction
Hazardous to the environment

A substance can be characterized by a maximum of three danger symbols; one for physicochemical effects, one for biological effects, and one for environmental effects. Figure 2 shows the 10 danger symbols used to identify the 15 danger categories enumerated above.

There is no exact correspondence between the danger categories and the danger symbols, in the sense that in several cases the same symbol is used to characterize more than one danger category (e.g., the skull-and-crossbones used for very toxic, toxic, carcinogenic, mutagenic, and substances toxic to reproduction; or the St. Andrew's cross for harmful substances, irritants, substances producing sensitization on inhalation, Category 3 carcinogens, Category 3 mutagens, and Category 3 substances toxic to reproduction). The symbol thus provides only preliminary generic information on the type of risk; the real danger of the substance is indicated only by the danger indications and risk phrases (R). The safety instructions (S phrases) provide information on the specific precautions to be taken during handling, and first-aid measures in case of accidental contamination or ingestion.

The classification criteria provide a way of utilizing the physicochemical, toxicological, and ecological data on a substance most effectively for assigning danger symbols, risk and safety phrases.

Classification Based on Physicochemical Effects. A substance is classified as explosive if it falls within at least one of the three criteria: shock, friction, or heating. A substance is extremely flammable if it is a liquid with flash point $<0\,^{\circ}C$ and boiling point $\leq 35\,^{\circ}C$, or if it is gaseous and becomes flammable on contact with air at ambient temperature and pressure. A substance is highly flammable if it is a liquid with flash point $0-21\,^{\circ}C$, or if it is a solid capable of igniting and continuing to burn after the source of ignition is removed. A substance is flammable if it is a liquid with flash point $0-55\,^{\circ}C$.

A substance is an oxidizing agent if it responds positively to a specific test designed to check its potential to increase flame propagation velocity in a sample of combustible substance.

Classification Based on Biological Effects. With regard to the lethal acute effects the LD_{50} or LC_{50} values for the appropriate species are used; normally, oral and inhalatory studies on rats and cutaneous studies on rabbits or rats are preferred.

Table 2 gives reference values for danger classification and, within the scope of such a classification, the distinction between the categories of very toxic, toxic, and harmful. For the inhalatory route, two separate sets of reference values are given, depending on the physical state of the substance; in the majority of cases it is practically impossible with powdery solids and high boiling point liquids to prepare suspensions or aerosols of concentrations >5 mg/L.

In order to reduce the number of animals subjected to experimentation, the "fixed-dose" method has recently been developed for the determination of acute toxicity, based on determining not the lethal dose, but the "discriminating dose", i.e., the dose that produces toxic, but not lethal effects. Reference values (mg/kg body weight) are:

Very toxic	<5
Toxic	5
Harmful	50 – 500

As regards long-term effects, a substance is classified as toxic or harmful if repeated or prolonged exposure can produce serious damage (evident functional disturbances or morphological changes of toxicological significance) below specified dose levels. With regard to subchronic toxicity studies, i.e., at 90 d, reference values are:

Figure 2. Symbols used to identify danger categories within the EU classification system

Table 2. Reference values for danger classification based on animal tests

Category	LD_{50}, oral in rat, mg/kg	LD_{50}, dermal in rat or rabbit, mg/kg	LC_{50}, (inhalatory) in rat, mg/L for 4 h	
			Aerosols or particulates	Gases and vapors
Very toxic	≤ 25	≤ 50	≤ 0.25	≤ 0.5
Toxic	25 – 200	50 – 400	0.25 – 1	0.5 – 2
Harmful	200 – 2000	400 – 2000	1 – 5	2 – 20

Oral route, rat: $\leq 50\,\mathrm{mg\,kg^{-1}\,d^{-1}}$
Cutaneous route, rat or rabbit: $\leq 100\,\mathrm{mg\,kg^{-1}\,d^{-1}}$
Inhalatory route, rat: ≤ 0.25 mg/L, 6 h per day.

For subacute toxicity studies, i.e., at 28 d, these values are multiplied by 3.

In a chronic toxicity study, which normally lasts the whole life of the animal (2 years for rats), it is not possible to give individual refer-

ence values, and the evaluation is made case by case.

When an individual reference value is given, it is possible to distinguish between toxic and harmful effects from the dose level at which the toxic effect is observed; if it is slightly below the reference value, the substance is classified as harmful. However, if it is significantly below this value the substance can be classified as toxic. The EU classification reserves the category of very toxic for acute lethal or nonlethal effects.

With regard to local effects (corrosive and irritant) criteria are defined for assigning specific risk wording depending on the type of effect and its severity. For corrosive effects, it is possible to use two different risk wordings, depending on the time it takes a substance to destroy the whole thickness of the cutaneous tissue (between 3 min and 4 h).

A substance is classified as a skin irritant if it produces significant cutaneous inflammation that lasts for at least 24 h following a maximum exposure time of 4 h; such inflammation is regarded as substantial if the scores obtained separately for the occurrence of erythema, eschar, or edema, are greater than the arbitrarily specified limiting values.

With regard to effects on the eyes, a distinction may be made between serious ocular lesions and ocular irritation, depending on the scores obtained for four specific end points:

Opacity of the cornea
Lesion of the iris
Redness of the conjunctiva
Edema of the conjunctiva

It is also possible to classify a substance as a respiratory tract irritant, but since no experimental models are available to evaluate such an effect on laboratory animals, it has to be based on practical observations mainly connected with the professional use of the substance.

For cutaneous sensitization, a reference method (maximization test) exists based on the guinea pig; a positive response in at least 30 % of the animals tested classified the substance as a skin sensitizing agent. There is no experimental model for sensitization by inhalation: in this case tests have to demonstrate reliably that the substance can produce a sensitization reaction in subjects by inhalation, at a frequency greater than that encountered in a control population.

There are three danger categories with regard to carcinogens:

Category 1: substances known to be carcinogenic in humans on the basis of epidemiological studies
Category 2: substances for which there is sufficient evidence of carcinogenesis in experimental animals (as a precaution, such substances are labeled as being in Category 1)
Category 3: substances to be regarded as suspect with regard to possible carcinogenic effects in humans on account of a positive, but inconclusive response in experimental animals

Three danger categories are defined for mutagenesis:

Category 1: substances known to have mutagenic effects in humans. There is sufficient evidence to establish a causal relationship between human exposure and the occurrence of hereditary changes (up to now no substances fulfilling such criterion are known). Moreover, it is extremely difficult to obtain reliable information from studies on the incidence of mutations in the human population, or on a possible increase in frequency.
Category 2: substances for which there is sufficient evidence to say that it is probable that human exposure will lead to the development of hereditary genetic changes. It is necessary to obtain positive results from studies demonstrating the mutagenic effect on mammalian germ cells in vivo or the mutagenic effect on somatic cells, which together clearly demonstrate that the substance, or one of its metabolites, is capable of reaching the germ cells.
Category 3: substances to be considered as suspect with regard to possible mutagenic effects, based on positive test results that demonstrate the mutagenic effect on mammalian somatic cells in vivo, normally supported by positive results of mutagenesis tests in vitro.

For reproductive toxicity, the effects on both fertility and development must be borne in mind. Three danger categories are defined for each of these effects.

1) Effects on fertility:

Category 1: substances capable of reducing human fertility, as demonstrated by epidemiological studies
Category 2: substances capable of affecting human fertility, based on clear evidence from animal studies of reduced fertility in the absence of toxic effects
Category 3: substances that give rise to concern about possible effects on human fertility, based on animal studies demonstrating a decrease in fertility, but not providing sufficient evidence to justify classification in Category 2

2) Effects on development:
Category 1: substances capable of producing harmful developmental effects in human progeny as shown by epidemiological studies
Category 2: substances that can produce harmful developmental effects in human progeny, based on unequivocal results in suitable animal studies, in the absence of maternal toxicity
Category 3: substances that give rise to concern on account of the possible effects on human progeny based on animal studies showing harmful developmental effects in the absence of maternal toxicity, but not providing sufficient evidence to justify classification in Category 2

Classification Based on Environmental Effects. Criteria have been defined at EU level for classifying chemical substances according to their potential environmental hazard. Such criteria essentially refer to the aquatic compartment, at present considered representative of the whole ecosystem. Three parameters are taken into consideration:

Effects on aquatic species
Bioaccumulation capacity
Degradation

Effects on Aquatic Species. Normally these refer to acute effects, even if under some conditions the long-term toxicity data can modify the classification obtained from the acute effects. The species used are:

Fish (LC_{50}, 96 h);
Daphnia (EC_{50}, 48 h);
Algae (IC_{50}, 72 h);

The cut-off toxicity values that define the various subcategories are 1, 10, and 100 mg/L, intended as concentrations in the aquatic medium.

Bioaccumulation Capacity. Normally, a substance is regarded as capable of bioaccumulation if $\log P_{ow} \geq 3$, unless the experimental bioconcentration factor $BCF \leq 100$.

Degradation. A substance is regarded as rapidly degradable if one of the following criteria is satisfied:

1) In a 28-d degradation study, a 70 % degradation is obtained if the test is based on the measurement of dissolved organic carbon, or 60 % of the theoretical maximum value if the test is based on measuring the loss of oxygen or formation of carbon dioxide. These biodegradation levels should be reached within 10 d of the start of degradation, i.e., from the moment at which 10 % of the substance is degraded.
2) In cases in which only the COD and BOD_5 are available, the ratio between the two $BOD_5/COD \geq 0.5$.
3) Data exist, demonstrating that the substance can be degraded (in a biotic or abiotic manner) in an aquatic environment to levels >70 % within 28 d.

3.4. Hazard Identification of Preparations: Calculation Systems for Different Use Categories (EU Approach)

For intentional mixtures of chemical substances (preparations), the problem of hazard identification may be particularly acute given the widespread commercial availability of chemical products, definable as preparations, intended for a wide variety of uses, including domestic environments, where those particularly at risk (children, the elderly) can come into contact with such products and suffer harmful effects. The possibility of human exposure is extremely variable, depending on the intended use of the product. The potential danger of a preparation depends on the danger characteristics of its components and their concentration in the product. Such a danger can essentially be evaluated in two ways:

1) By subjecting the preparation to a series of experimental tests to determine the toxicological and ecotoxicological properties and physical effects, in the same way as for a substance
2) By employing calculation methods that take account of the danger of the various components and their concentrations, normally expressed in wt % (assuming the absence of synergistic or antagonistic phenomena)

Some categories of preparations, because of their intended use, are subject to extremely stringent regulations that require a series of experimental studies to determine the potential danger to humans and, in some cases, to the environment (e.g., for pharmaceuticals and agricultural pesticides). In the majority of cases, however, evaluation of the potential danger is the responsibility of the manufacturer or importer, who is basically free to choose between the experimental and calculation options, with a clear preference for calculation, given the extremely high cost of performing a set of experimental studies. A series of norms has recently been approved at international level that aim to discourage, or at least minimize, experimental studies on animals, for humanitarian reasons.

In the past, a series of specific technical norms has been defined at EU level for particular areas of use (solvents, paints, inks, pesticides), which besides sanctioning the principle of alternative between biological testing and application of a calculation system, define specific mechanisms for establishing the danger classification of the preparation, depending on the nature and proportions of its components. Directive 88/379/EEC [9] is a first step in the unification and rationalization of such systems to arrive at a single evaluation mechanism regardless of the intended use of the product.

3.4.1. Classification Based on Physical and Chemical Effects

No calculation system exists that enables the flammability, explosiveness, and oxidizing power of a preparation to be evaluated, depending on the presence of components exhibiting such properties. The characteristics of the preparation are largely influenced by the chemical nature of the other components. For example, if a liquid preparation contains 20 – 30 % of a flammable substance, it is likely that the preparation will exhibit such characteristics if the other components are nonflammable liquid organic substances, whereas if the preparation contains a large amount of water it is highly probable that this will inhibit flammability. Therefore, in the case of chemical and physical effects, the preparation should be tested as if it were a substance, and eventually be classified according to the experimental results. Not all preparations are to be tested, only those that contain components exhibiting such properties above specific limiting concentrations.

3.4.2. Classification Based on Biological Effects

Given that it is possible to evaluate biological end points by means of experimental tests on the preparation, it is permitted to use a conventional calculation system. Such a system is based on the assumption that the components of the preparation have previously been evaluated and, if considered dangerous, have been correctly classified and labeled. The starting point of the classification of preparations is therefore classification of its components; if a substance is classified in different ways by different manufacturers and importers, such variation will be reflected in preparations containing that substance.

Another basic feature of the calculation system of Directive 88/379 is that each specific effect is evaluated separately, with the possibility of assigning to a substance not just an overall percentage limit, but various limits depending on the specific effects of the substance, and reflected in the risk wording assigned to the latter. For each substance, at the time of its official classification by the group of EU experts it is possible to define specific percentage limits, depending on the various effects of the substance, which are applied when the substance is present in a preparation. Figure 3 shows a file card relating to acrylonitrile, characterized by various types of effect [6]. The card includes identification data, structural formula, chemical name in the various Community languages, classification, labeling, and the various percentage limits

to be adopted when the substance is present in a specific concentration in a preparation.

Only a minority of substances have been assigned specific percentage limits, but Directive 88/379 allows the calculation system to be employed, having defined a series of generic limits (established according to the toxicological significance of each effect and independent of the chemical nature of the substance). Table 3 summarizes the percentage limits to be employed, depending on the classification of the components of the preparation. For gaseous preparations, the percentage figures are preferably given by volume rather than by weight.

3.4.3. Classification Based on Environmental Effects

The Directive does not provide for the possibility of classifying a preparation according to its potential environmental danger. A proposal to introduce such criteria is currently under examination. The aim is to define specific percentage limits depending on the risk phrase assigned to the substances. The possibility of determining experimentally the characteristics of the preparation would be limited to the effects on aquatic species, since it is technically impossible to determine log P_{ow} and biodegradability of a preparation. In order to demonstrate experimentally that the preparation is not toxic to aquatic species, it is necessary to carry out tests on all the three species, fish, *Daphnia*, and algae.

4. Risk Assessment

4.1. General Methodology

Risk assessment comprises one or more of the five steps defined in Chapter 2. The fundamental

principle is that risk depends on the inherent hazardous properties of a substance and the extent of exposure to that substance. Consequently, a risk assessment can be concluded at a relatively early stage if it has been demonstrated that a substance exhibits no hazardous properties or that neither humans nor the environment will be exposed to it. The following scheme illustrates the steps and the relationships between them.

Information gathering

Effects	*Exposure*
Hazard identification; dose (concentration) – response (effect) assessment, if appropriate; toxicokinetics	Human exposure assessment (workers, consumers, via the environment, as appropriate); environmental exposure assessment (water, soil, air, as appropriate)

↓

Risk characterization

Human health	*Environment*
	Evaluation of effects data and comparison with exposure data

↓

Outcome of risk assessment

A risk assessment should be amenable to revision in the light of any new information.

4.2. Qualitative and Quantitative Aspects: Toxicological and Ecotoxicological Properties

The definitions in Chapter 2 of risk characterization and risk estimation illustrate the distinction between the qualitative and quantitative aspects of risk assessment. It is sometimes useful to be able to quantify a risk as a numerical probability; equally, it can sometimes be misleading and often impossible. A qualitative characterization of risk, however, should be included in any assessment in which data on intrinsic properties have been compared with data on exposure.

4.2.1. Hazard Identification

The principal toxicological and ecotoxicological properties which should be considered in a hazard identification are described in Chapter 3. If it can be demonstrated that a substance is not inherently hazardous, it is appropriate to conclude that it poses no risk without proceeding to an exposure assessment.

4.2.2. Dose (Concentration) – Response (Effect) Assessment

This step cannot always be separated from hazard identification. Ideally, it should be a quantitative exercise in which an assessor determines the dose or concentration at or below which an adverse effect is unlikely to occur.

In relation to toxicological properties, such a threshold level can be determined for subacute, subchronic, or chronic toxicity, for reproductive toxicity, and for nongenotoxic carcinogenicity. For most other effects, it is usually impossible or inappropriate to determine such a level, and only a qualitative assessment of a substance's inherent capacity to cause such effects can be made.

In relation to ecotoxicity, particularly aquatic toxicity, it is possible to calculate a predicted no-effect concentration (PNEC) by applying an assessment factor to an experimentally derived toxicity value, such as the LC_{50} or NOEC (see Section 3.1.3). An assessment factor is an expression of the degree of uncertainty in extrapolation from test data on a limited number of species to the environment; it should be adjusted according to the extent and quality of the data.

4.2.3. Exposure Assessment

Ideally, exposure assessment should result in the estimation of an exposure level or predicted environmental concentration (PEC). For chemical substances and products already on the market and in use, it should be possible to measure actual exposure levels and concentrations. When conducting a risk assessment before marketing or use, it is usually necessary to predict exposure on the basis of information such as the properties of the substance, its use pattern, and the expected frequency and duration of exposure. Sometimes it is not possible to achieve a quantitative estimation and a qualitative estimation must be made instead.

Exposure assessment should take account of the three principal human populations (workers, consumers, and those exposed indirectly via the environment) and the three principal environmental compartments (water, soil, and air). A risk assessment can be concluded and a substance deemed to pose no risk if there is evidence that neither humans nor the environment

will be exposed to it. If it can be demonstrated that a particular population or compartment is not likely to be exposed to the substance, exposure assessment and risk characterization for that compartment or population are unnecessary.

4.2.4. Risk Characterization

If dose (concentration) – response (effect) assessment and exposure assessment have been conducted quantitatively, it should be possible to compare a human exposure level with a threshold level for toxicological effects or a PEC with a PNEC and to determine an exposure/effect ratio. If only a qualitative assessment of effects or exposure has been made, the comparison will have to be made in more qualitative terms.

Where a threshold level for toxicological effects has been determined, it may be appropriate to apply an assessment factor to that level before comparing it with the exposure level. The assessment factor should take account of the following elements:

1) Nature and severity of the effect
2) Uncertainties in experimental data, including interspecies variations
3) Different susceptibilities in exposed humans
4) Extent to which exposure can be controlled and monitored in different human populations (workers, consumers, those exposed indirectly)

On the basis of the comparison of effects and exposure, whether quantitative or qualitative, the assessor should establish the degree of concern associated with the substance and whether further action is necessary, possibly including recommendations that further information on effects or exposure be acquired so that the risk assessment can be repeated and the risk characterized more precisely. As indicated above, risk estimation (quantification of the likelihood of adverse effects) is not always possible or appropriate.

4.2.5. Physicochemical Properties

As indicated in Section 3.1.1, flammability, explosiveness, and oxidizing potential are the three physicochemical properties which correspond to direct adverse effects. The procedures for assessing risk in relation to those properties are not entirely analogous to those for toxicity and ecotoxicity. The dose (concentration) – response (effect) step is not applicable. The concept of an exposure level is meaningless in relation to physicochemical effects, so exposure assessment amounts to determining the reasonably foreseeable conditions of use; risk characterization then entails evaluation of the likelihood that an adverse effect will occur under those conditions.

4.3. Risk – Benefit Considerations

The outcome of a risk assessment can be that measures should be taken to reduce the risk posed by a substance. The process of deciding precisely which measures are appropriate falls outside the scope of risk assessment. Socioeconomic and political considerations may influence decisions on risk reduction; it is therefore important that risk assessment, based solely on technical data, should be clearly separated from that process.

This applies especially where the withdrawal of a substance or product from the market is being considered. It may be appropriate to weigh the risk which would thus be removed against the benefits which would be forgone. A substance may be necessary to the safe operation of an industrial process for which no satisfactory alternative is available; withdrawal of that substance to remove a toxic risk identified in the risk assessment may create a new risk to worker safety. In other cases, the benefits of the risk reduction itself may be compared with its costs in order to assess whether they are proportionate; if the costs are judged to outweigh the benefits, it may be decided not to reduce the risk or to employ risk reduction measures (e.g., exposure limits) which stop short of withdrawal of the substance.

The allocation of a financial cost to a risk is very difficult and likely to entail subjective judgment. Decisions not to reduce a risk or to take only limited risk reduction measures imply the concept of "acceptable risk."

4.4. Definition of Acceptable Risk

It is extremely difficult, if not impossible, to achieve a general definition of acceptable risk;

acceptability is inherently subjective and variable. In individual cases, it may be useful to quantify the risk (see Section 4.2.4).

Perception of a risk by those subject to it is a highly significant factor. There is evidence that high risk may be considered acceptable if it is perceived as controllable and dependent on personal choice (e.g., car driving, smoking). The risks due to exposure to toxic substances in chemical products, even if quantified as very low, may be considered unacceptable by the public because they are perceived as being beyond its control.

The level of probable damage to humans and the environment by a substance must be viewed in relation to the advantages which its use offers to society. This is difficult, since the groups who have to bear the risk are not the same as those who draw benefit from the product. An abstract definition of the benefit is not as a rule possible, since such a definition varies greatly between individuals, and also depends on sociopolitical conditions. The process of weighing up risks and benefits, which ultimately leads to a definition of the acceptance of a certain risk, is thus often extremely blurred and determined by political motives. It is frequently the case that bodies are entrusted with this task in which relevant, social groups are represented, but it is not feasible for such an assessment to be carried out for every chemical substance. Conventions are, therefore, often established for this evaluation, but the reasons for the final decision are nevertheless frequently of a purely political nature.

Most experience gained in the field of risk – benefit examination has been in pharmaceuticals, since the benefit can usually be very clearly defined, and it is known that harmful side effects cannot be completely avoided. Things are far more problematical in the industrial chemicals field, substances with irreversible effects and without a NOEC being the most difficult to deal with.

A classic example is formaldehyde, which is known to be capable of causing a sensitizing and carcinogenic effect. Because it is indispensable for technical purposes, it is accepted that below certain statutory limits it may continue to be used, even in consumer articles, although adverse effects cannot be precluded, at least in particularly sensitive persons. As a rule, an attempt is made to focus on risks to which humans or the environment are unavoidably exposed. It was calculated, for example, that the occurrence of ethylene oxide as a micropollutant in cosmetic raw materials does not result in a significant increase in this substance in the human metabolism, and that these traces can be regarded as harmless.

Examples in the ecological field are chelating agents such as ethylenediaminetetraacetic acid (EDTA) and nitrilotriacetic acid (NTA), for which it is feared that heavy metals present in sediments in surface waters may be remobilized. An attempt is being made by monitoring programs to ensure that these substances do not accumulate in surface waters in concentrations at which such an effect might arise.

Since many of these effects are highly speculative and elude quantitative assessment, any risk – benefit examination inevitably remains blurred and open to considerations of political expediency. Bans or restrictions on chemical products, which would result in considerable economic consequences, have to a large extent not been imposed.

4.5. Summary of Risk Assessment

The present state of the scientific art – even in toxicology with its rather long tradition, and even more in ecotoxicology – does not allow a real quantified risk characterization which might be used as basis for the definition of an acceptable risk, as practiced in particular in the United States. Attempts to compare risks, identified and characterized as outlined above, with other risks in normal life are seldom successful because society has a different perception of various risks.

A pragmatic approach is appropriate, and should embrace the following elements:

1) Identifying chemicals for which the risk, due to minimal hazardous effects or to minimal exposure, is obviously negligible
2) Refinement of data bases for which this decision cannot be taken on the basis of available data
3) Quantification of risk characterization, as far as possible case by case by expert judgment, for chemicals which show a significant risk potential
4) Decisions on risk reduction measures by political bodies on the basis of acceptability of

risk, taking account of economic and social considerations

5. Risk Management

Risk management should flow logically from risk assessment, but is separate from it. Risk assessment should have characterized the risks, have identified who or what is at risk, and the levels, sources and pathways of exposure. The function of risk management is to reduce the risks and to mitigate the consequences if an adverse event occurs.

It may be possible to eliminate a particular risk, but more usually a residual risk remains, and the challenge is to reduce this to an acceptable level. Science has a role in defining this level, but socioeconomic and other factors are more important, and outside the scope of this article. Those wishing to explore the subject further will find useful starting points in references [10], [11].

There can be no single system of risk management. The key to successful risk management is the selection of the most appropriate set of tools for particular situations and their acceptance by those causing the risks and by those most likely to be affected by them.

Although this article is principally concerned with products control, there are instances where products are only one source of exposure and the risk assessment has to consider the overall impact arising from all sources. Lead is an example of this; there is concern about the effects, particularly on children, of uptake of lead into the body from a range of sources through various pathways. Products control can reduce exposure but cannot eliminate the problem. A much larger range of measures is needed.

In the context of chemicals control, hazard is an inherent property of a chemical but risk depends on the extent of exposure. Exposure is a function of variable, controllable elements (how the chemical is made, how it is incorporated into a product, and how that product is used).

The more important tools for the management of risks from chemical products are dealt with below.

5.1. Supplying Information (Risk Communication)

This is a fundamental requirement in all strategies for managing risks. Unless all those making, taking, or regulating the risks, i.e., the "stakeholders", are aware of the risks, their consequences, and what they can do to reduce these, the strategy will be flawed. Thus:

1) Those creating risks are often best able to take steps to reduce them. They need to inform themselves about the risks associated with their activities and products, and about the possible consequences of the risks. They also need to know what can be done to reduce the risks and to mitigate the consequences.
2) Those who might be affected are more likely to find the risks acceptable if they know what the risks are and what measures have been taken to minimize them. They also need to know what they themselves can do to reduce the risks and the possible consequences.
3) Those responsible for regulating the activities or products which create the risks need to have as much information as possible relating to the risks and about the tools available to reduce them.

Ensuring safety during the manufacture of chemicals, and products containing them, is primarily a matter for industry and the appropriate regulators: safe use in industry and commerce involves management and workers. Outside the workplace, individual behavior becomes the most important factor, and is greatly influenced by personal knowledge, experience, and perception of the risks.

Much environmental, consumer safety, and worker protection legislation requires those producing, importing, and supplying products to give information on the hazardous properties and risks associated with their products, and there is provision for such information to be passed down the manufacturing and supply chain. This is a feature in much EC, Scandinavian, and North American legislation. The most obvious manifestation is the information that appears on labels or is supplied as safety advice with the product. Labels usually carry information of different kinds and give only very basic information on risks, but they may be the

only means of influencing user behavior, which is often important in determining whether a risk becomes manifest. Effective labeling is very important.

Labeling requirements are generally linked to a classification system. These systems cover a range of hazards, e.g., toxicity, irritancy, flammability, effects on the environment, and set criteria to define degrees of hazard, e.g., very toxic, toxic, harmful. The information required on the label, often in the form of standard "risk phrases," follows from this classification. Packaging requirements, which can be important in reducing risk (e.g., through accidental exposure) may also be linked to this classification, as in the EU. Labels are primarily intended to warn and protect the user but, to an increasing extent, include information on environmental safety, in particular on safe disposal.

Labeling is frequently supplemented by data sheets which provide more detailed information. Chemical manufacturers often supply data sheets to their workers, to their customers who process chemicals into products, and to the emergency services. Legislation in the EU on the safe handling of chemicals requires the provision of information in this form. The preparation of international data sheets, principally for worker protection, is a feature of the International Programme for Chemical Safety, a collaborative program involving the World Health Organization, International Labour Office, and United Nations Environment Programme.

Access to information on the hazardous properties of chemicals and on exposure has improved in recent years in most countries. Some countries (e.g., the United States) have legislation requiring such information to be made available. The EC Directive on access to environmental information [12] should ensure greater availability and easier access within the EU to information held by public authorities. Public interest groups have campaigned for greater freedom of access to information, and often act as alternatives to official or industrial sources of information on risks (often seen as less biased or more independent).

5.2. Codes of Practice

Since the way in which products are used can by very important in terms of protecting human health and the environment, codes of good practice are often developed for the more dangerous substances to help ensure safe use. These give guidance on good practice in the use of products and the safe disposal of any wastes. In some countries, demonstration that such codes have been followed is a valid defense in the event of legal proceedings. Failure to comply with a code may lead to prosecution.

5.3. Product Standards

These are usually intended to ensure that a product delivers the required performance, but they can also reduce the impact on human health and the environment, e.g., by specifying maximum levels of dangerous impurities. Conversely, by specifying a performance which can be met only through the use of a dangerous substance, or by failing to revise obsolete standards which encourage the continuing use of dangerous substances, needless risks can be created or perpetuated.

5.4. Control of Supply

This includes control of production and importation. Prevention of entry into the manufacturing and supply chain is among the most powerful and effective forms of product control. Control of production has been used to control the supply and hence the eventual release of chlorofluorocarbons, but control at the point of sale is more common. The latter is widely used as part of approval schemes for pesticides and pharmaceuticals, etc. (e.g., particularly dangerous substances and formulations may be supplied only to professional users). It is also common in EU Member States to implement EU controls on marketing and use, e.g., wood preservatives containing pentachlorophenol cannot be sold to the public in the EU, and the supply for professional use is strictly limited. Lead-based paints may be supplied only for use on specific historic buildings in the United Kingdom.

Attaching conditions to the supply of a chemical rather than banning it outright can be an effective means of control, while allowing appropriate uses. Many of the pesticides available to the public must be supplied in small packs or in diluted form.

Controls on supply are fairly easy to enforce (suppliers can be readily identified, and most are already subject to other forms of control, e.g., inspection by environmental, consumer protection, or labor protection authorities). However, controlling supply has no impact on products already in the control of users. This is why it is often seen as a weaker form of control than control of use (see Section 5.5).

5.5. Control of Use

Although potentially a more powerful form of control, control of use is more difficult than controlling supply. Control of use by an individual may involve changing behavior or interfering with personal rights, preventing the individual from obtaining the product in the first place is a more effective option. But control of use, if it can be enforced effectively, addresses the control of products already in the possession of the user. Many countries have laws which seek to control use by individuals. To help prevent illegal use or disposal, public information and recovery schemes may be introduced to encourage those holding stocks of the product to return them to the supplier or to a body designated for their safe disposal.

Controlling use by industry and business is more feasible. They can be more readily identified, targeted, and the controls enforced by labor or other inspectors.

5.6. Voluntary Agreements

Regulations can be expensive to develop and implement, and often follow rather than force change. By the time regulation takes effect it is likely that industry has adjusted its processes, withdrawn problematic products, and is marketing alternative products. Voluntary agreements sometimes offer a more cost-effective alternative. Paint manufacturers in the United Kingdom agreed to stop using lead driers in paints intended for home use: it is claimed that the voluntary agreements associated with the Toxic Release Inventory in the United States have significantly reduced releases of chemicals to the environment. All the principal manufacturers or suppliers must be parties to such agreements, which must be clear, set targets and timetables, and include systems for monitoring progress. They should be public documents. Even if voluntary agreements are replaced by regulations, they can provide valuable experience which helps avoid problems in implementing the regulations.

5.7. Economic Instruments: Harnessing Market Forces

There is a growing interest in measures to achieve environmental ends through market mechanisms; these can either replace or complement regulation. There are few examples in the field of chemicals control, but tax differentials on motor fuels containing lead additives or to encourage the use of diesel fuels have been adopted in a number of countries.

The attractions of economic instruments are that they highlight that the "polluter is paying," encourage the market to allocate the substance concerned to more essential uses, and provide an incentive to develop substitutes.

Probably the most significant examples of the power of market forces for environmental benefit do not involve government intervention at all. "Green consumer" campaigns can claim many successes, including reducing the use of chlorofluorocarbons in domestic products. Many retailers have recognized the selling power of "environmentally friendly" products and require their suppliers to produce products which exploit this. The ecolabeling schemes now being introduced in the EU and elsewhere will further enhance this trend.

5.8. Integration of Pollution Control and Chemicals Control

Chemicals control deals with problems arising from chemicals as products–pollution control is concerned with chemicals (and other agents) in waste streams. Insofar as the overall problem is from chemicals released to the environment, chemicals control and pollution control complement one another.

In 1991, the OECD adopted a Council Recommendation on "Integrated Pollution Prevention and Control" which commits Member

States to "take into account the effects of activities and substances on the environment as a whole, and the whole commercial and environmental life cycles of substances when assessing the risks they pose and when developing and implementing controls to limit their release." Based on this Recommendation, the Commission of the European Communities is preparing a Union proposal which should lead to greater coordination of the control of waste streams from the chemical and related industries. It should also facilitate the integration of pollution control and chemicals control. Some European countries, e.g., United Kingdom, The Netherlands, Sweden, have already enacted such legislation, but none have gone as far in that direction as the OECD Recommendation implies.

Where total exposure to a substance is important (e.g., lead) and there is a significant contribution from industrial emissions, more effective control of industrial waste streams must clearly be part of the overall risk management strategy.

5.9. Monitoring Effectiveness

The principal requirement is for systems which monitor the effectiveness of the measures taken. It is important that the initial risk assessment be used to define a baseline against which progress can be assessed, and that risk management strategies provide a framework within which progress can be measured. Such a framework should set clear objectives, targets, and timetables which address questions such as:

– Are the measures reducing or containing the risks?
– By how much and to what timescale?
– What are the costs–to all the stakeholders?
– Does more need to be done or can efforts be relaxed?

It may be possible to measure directly whether or not risks have been reduced, e.g., from accident statistics, measures of mortality and morbidity, recovery of species and ecosystems. In many cases, reduction in exposure of the "at-risk group" will be measurable, implying a reduction in the risk, in other cases reduction of inputs to pathways and environmental compartments (air, water, etc.) will be the best that can be achieved. Monitoring programs such as these will answer the first two questions. Normal financial practices, if set up appropriately, can begin to answer the third question, but it is important that all the costs are exposed, including the costs of not taking action, for all those affected. The various stakeholders may differ in their ability to monitor and calculate their costs, and placing a monetary value on environmental damage or improvement remains a difficult problem for economists (some costs are readily monitored while others remain difficult). Nevertheless, cost considerations cannot be avoided.

The final question can only be answered following an assessment of the kinds of information referred to above. The answers represent the outcome of the "feedback loop" which should be an integral part of all risk management strategies.

6. Ecolabeling

6.1. Philosophy

There has been a growing recognition over the past decade that it is not just for public authorities to set rules for environmental behavior. Companies should include the environment in their strategies, over and above the minimum regulatory requirements. Consumers can also play their part by stimulating (by individual choice) the production and marketing of more environmentally friendly products.

The objectives underlying ecolabeling schemes are generally:

1) To provide purchasers with guidance on choosing products with least impact on the environment
2) To encourage the development of products with less impact on the environment, but which still meet the customers' requirements on costs and effectiveness
3) To harness purchasing power to complement regulatory and other controls aimed at protecting and improving the environment

The German "Blue Angel" (Blauer Engel) scheme, set up in 1978, is an early example of a successful ecolabeling scheme, but in the last few years there has been an upsurge in interest in such schemes. Public awareness of environmental issues has been raised, and more and more of

the public want to play a part in preventing or dealing with environmental problems; industry has come to realize that being seen to be "environmentally friendly" helps to sell products, and governments have recognized that consumer purchasing power can be useful in securing environmental improvement. However, the proliferation of labeling schemes and unsubstantiated claims by manufacturers about the "greenness" of their products may confuse, rather than inform, the public. There has also been concern that national schemes might become barriers to international trade. An EC Regulation was agreed in March 1992 [13] and the members of the Nordic Council, Finland, Norway, and Sweden, agreed to set up a joint scheme in November 1989. In North America, the Canadian Government set up its "Environmental Choice Program" in 1988 which, for the first time, adopted a "cradle-to-grave" approach–a concept subsequently adopted by the EU and by the Nordic countries. This approach requires a life-cycle analysis of the product (the EU scheme uses the indicative assessment matrix, Fig. 4).

All existing schemes have restrictions on the types of product covered, e.g., food, drink, and pharmaceuticals are excluded from the EU scheme. Products falling within a scheme are divided into product categories or groups (e.g., washing machines, paints, detergents) and criteria to evaluate the environmental impact of each category are published. Manufacturers who believe that their products meet the criteria may submit them for approval and, if successful, can display the appropriate label or logo on the product and packaging and use it in advertisements and promotional material.

The criteria for award of an ecolabel can be separated into those of a general nature (e.g., legal health and safety requirements) and those that are specific to a particular kind of product. Chemicals per se are unlikely to qualify for any of the product groups in any of the schemes, but they are components of a great many of the products which are eligible for consideration (e.g., adhesives, paints, detergents), and there are many examples where the chemical content can have a bearing on whether or not a product is eligible for the award of an ecolabel. Under the Nordic scheme, no product can be awarded an ecolabel if it contains substances which do not decompose or which bioaccumulate. The Canadian criteria for adhesives prohibit the award of a label to products containing aromatic hydrocarbons, formaldehyde, or chlorinated solvents. The Nordic criteria for detergents limit the content of phosphates, EDTA, NTA, and sodium perborate to less than 0.2 %, and exclude products containing carcinogenic, allergenic, and teratogenic substances.

6.2. The EU Scheme

The scheme was officially launched on June 30, 1993 with the adoption of the first sets of ecological criteria relating to washing machines and dishwashers.

The objectives of the scheme are:

1) To promote the design, production, marketing, and use of products which have a reduced environmental impact throughout their entire life cycle
2) To provide consumers with better information on the environmental impact or products

All consumer products, in principle, are eligible under the scheme, with the exception of food, drink, and pharmaceuticals. Consumers in this context are defined broadly to include business purchases.

The award of the ecolabel means that successful applicants are permitted to use the official logo (Fig. 5) on their approved products. A consumer faced with a choice of, say, washing machines of different makes can pick out, by means of this logo, those which have been shown to achieve a high standard of environmental performance. The same logo is used regardless of the type of product.

Figure 5. The EU official logo for ecolabeling

Environmental fields	Product life-cycle				
	Pre-production	Production	Distribution (including packaging)	Utilisation	Disposal
Waste relevance					
Soil pollution and degradation					
Water contamination					
Air contamination					
Noise					
Consumption of energy					
Consumption of natural resources					
Effects on eco-systems					

Figure 4. Assessment matrix for the EU ecolabeling scheme

The strength of the label is its European dimension. Once approved by one Member State, it can be used throughout the Community. This avoids having to make an application in every country where a national label exists, and thus avoids time-consuming and costly procedures. More importantly perhaps, the success of the EU scheme avoids a proliferation of national schemes, which might confuse the public, serve as barriers to trade and hamper the development of the Single Market.

The scheme should gradually improve the environmental performance and impact of products by giving recognition to those which are the most favorable to the environment. By providing the consumer with information essential to making a sensible purchasing decision, ecolabeling is beginning to make an effective contribution at EU level in the joint interest of consumers and the environment.

1. Production-Integrated Environmental Protection in the Chemical Industry

Jürgen Wiesner, Claus Christ, Wolfgang Führer, Dieter Stockburger

1.1. Introduction

The business of the chemical industry is to produce and sell chemical products. Profitability is therefore an essential aim of production. However, no chemical process exists that produces only the product desired. Other substances not desired by the producer are also formed in the gas, liquid, or solid state. These are referred to as residues.

Another equally important aim is to reduce the environmental effects of these residues to a level that is acceptable. Therefore, protection of the environment — both as an objective in its own right and as a duty involved in any forward-looking activity — is a constituent part of the managerial policy of the German chemical industry [1]. The European chemical industry has also committed itself to a strategy of environmental protection within the program of Responsible Care. The chemical industry endeavors to operate the production process so as to minimize the entry of residues and waste products into the environment, both quantitatively and with respect to their hazard potential, and to utilize raw materials and energy with maximum efficiency. This growing awareness of the environment follows not only from the principle that the chemical industry is responsible for its actions, but also from the changed conditions governing the introduction of new production methods and the operation of existing plants. These include the following:

1. The demanding international and national decrees and regulations covering environmental protection
2. In chemical companies, the correct allocation of costs required for “cleaning up” a given production unit to comply with regulations (e.g., the purification of waste gas and wastewater and the disposal of waste materials from this unit)
3. Difficulties in the disposal of waste materials due to the shortage of dumping space and the secondary costs of waste disposal plants
4. Costs of raw materials and energy
5. Increased public awareness of the importance of environmental protection
6. In addition, the processes and production plants of chemical technology must meet high standards of workplace protection and operational safety (⟶ Plant and Process Safety)

1.2. Formation of Residues in Chemical Processes

Chemical reactions do not lead exclusively to the desired product but also to residues which may pollute the environment. To understand the reasons for the formation of residues in chemical production processes, and to understand the possibilities for modifying these processes, the general conditions for chemical reactions must be considered. As an example an equilibrium reaction is considered in which a starting material A reacts with a reaction partner B to give a product P:

$$\mathrm{A + B + N \xrightarrow{M,C,H,E} P + P' + P'' + N'}$$

where A is the starting material, B the reaction partner, N a secondary constituent of A and B, N′ the reacted secondary constituent, M the reaction medium, C a catalyst, H an auxiliary, P′ a coupled product, E the energy, P the product, and P″ a side product or byproduct.

The term “residues” denotes all components that take part in the reaction and do not give the desired end product P.

Incomplete Conversion. In equilibrium reactions, components A and B do not react with each other to completion. One of the two substances A or B is generally used in excess to increase the extent of conversion to the other at equilibrium. Occasionally, the component present in excess is the reaction medium for the chemical conversion. The excess amount of A or B remaining at the end of the reaction can contain a higher or lower content of impurities, and must be disposed of in an environmentally friendly manner if it cannot be recycled directly after physical or chemical treatment.

Associated Substances or Impurities in Raw Materials. The appearance of byproducts or residues in chemical reactions can also be due to associated substances or impurities present in the starting materials. This applies especially to the winning of inorganic and organic basic materials from mineral, fossil, or biological raw materials. Examples of associated substances include the following:

1. Hydrogen sulfide in the processing of sour natural gases and mineral oils
2. Sulfur dioxide and dust emissions in the production of acetylene and synthesis gas by the formerly widely used coal-based processes
3. Contamination of wastewater by dissolved decomposition products of lignin (lignosulfonic acids, etc.) in the production of pulp from wood or other vegetable raw materials

Coupled Products. Another characteristic of many syntheses is the formation of coupled products P′, the quantity of which is coupled to the quantity of the main product P.

In inorganic syntheses, for example, the type of coupled product can depend on the form of the raw material component A in the available mineral or ore. For example, when sulfidic nonferrous ores are treated in pyrometallurgical processes, SO_2 is formed as the coupled product, and the coupled product $FeSO_4$ is formed during the digestion of ilmenite ($FeTiO_3$) in the production of the white pigment TiO_2 by the sulfate process. In the production of phosphoric acid from phosphate rock

by the sulfuric acid process the calcium and fluorine content of apatite even leads to two coupled products, namely, gypsum and hydrogen fluoride.

In organic syntheses, starting material A often contains a reactive group that is split off in the form of a coupled product during the reaction. In many cases, halogens or sulfonic acid groups are eliminated, forming acids or salts, and are replaced by other substituents. Also, selective reduction of organic compounds in aqueous solution by metals such as iron or zinc leads to formation of the corresponding metal salts or oxides as coupled products.

Byproducts or Products of Secondary Reactions. Byproducts P″ also reduce the yield of product and must be removed during the course of reaction or during processing of the reaction mixture. They can be formed by continuance of the reaction; e.g., in chlorination processes intended to produce monochlorinated compounds, higher chlorinated products can also be formed.

Reaction Medium. In chemical reactions and separation processes in the liquid phase (e.g., organic solvents or water), solutions or multiphase systems with at least one liquid component are present. The reaction medium or process medium M in these processes is either a solvent, and therefore not a contributor to the reaction, or both a solvent and a reaction partner, and is sometimes a catalyst.

Concentrated mineral acids (e.g., sulfuric acid or oleum) are often used in excess for digestion of inorganic raw materials or for production of reactive intermediates from relatively unreactive organic starting products. That proportion of acid not required for product formation must be either regenerated or disposed of in an environmentally friendly manner. Both routes are costly. Reprocessing is particularly difficult if the acid must be diluted or partially neutralized, or if salts have to be added to the solution in order to recover the product.

When water is used as the reaction medium, wastewater is produced that is sometimes highly contaminated with organic or inorganic substances.

Catalysts can also contribute to the formation of residues. Heterogeneous catalysts must be replaced when their activity is exhausted. In the case of homogeneous catalysts, either the catalyst component is removed along with the used process medium, or an additional processing stage is required to separate the used catalyst from the product.

Auxiliaries can be necessary in some reactions. Like catalysts, these take part in the process without being used up in the chemical reaction. For example, multiphase reactions sometimes require the use of surface-active agents to increase the interfacial surface area or accelerate the transfer of matter. These substances appear as residues or in wastewater when the reaction mixture is processed.

Process Energy. The process energy (electricity, heat) required must also be included in the environmental assessment of chemical processes. Generation of this energy from primary energy carriers also leads to emissions.

1.3. Environmental Concepts in the Chemical Industry

1.3.1. *The Concept of Integrated Environmental Protection*

In Germany, the concept of integrated environmental protection was introduced into the debate on environmental policy at the end of the 1970s [2]. It is being used to an increasing extent and is regarded as a mark of good environmental practice (e.g., in the report on the environment produced by the German Ministry of the Environment [3]). The term is defined differently in various social sectors. The following definitions are given as examples:

German Ministry for the Environment [4], [5]. Environmental protection must be integrated into all phases of the production cycle, i.e.,

1. Reduction or avoidance of harmful materials in the production process
2. Use of internal recycling and increase in energy efficiency in the production process
3. Development of alternative materials
4. Inclusion of the question of disposal in design of the product
5. Establishment of external recycling of production residues

Industrial Management [6]. The following measures should be put into effect:

1. Avoidance of additive end-of-the-pipe techniques where possible — that means process design that avoids or reduces residues
2. Control over the environmental effects of pre-stages and subsequent stages of the process
3. Cooperation with suppliers, consumers, and waste disposal agencies

Matter and energy balances for the process itself and its pre-stages and subsequent steps are taken into consideration when setting up these measures.

Institut für ökologische Wirtschaftsforschung (Institute for Ecological Economic Research), Berlin [7]. Integrated environmental protection techniques either do not cause environmental pollution compared with traditional techniques or do so to a lesser extent. Recycling is regarded as an integrated environmental protection method only if it is an integral part of the production process, i.e., if a closed- cycle operation is used that reduces emissions. If recycling occurs separately from the production process, it is regarded as an additive technique.

Statistisches Bundesamt (German Federal Bureau of Statistics) [8]. The term “integrated environmental protection” is not used in statistics. Instead, distinction is made according to those parts of fixed assets that are concerned with

environmental protection. The corresponding costs of a process change are also included in the statistics.

European Union [9]. The term “integrated techniques” includes

1. Clean production techniques
2. Processes based on materials that result in low environmental pollution
3. Reprocessing and recycling systems

Other Related Terms [10]. The terms “clean production processes,” “clean production,” and “clean technology” are used predominantly in English-speaking countries. *Clean production* goes to the roots of environmental problems, and minimizes both emissions and costs. *Clean technology* is more than a “set of clean production techniques;” rather it is an approach to provide users with services and other benefits enabling the environment to be protected from excessive pollution.

The following terms should also be mentioned: “best available technology” and “nonhazardous production.” However, none of these terms have been clearly defined or distinguished from each other.

Verband der Chemischen Industrie (VCI, Association of the German Chemical Industry) [11]. In integrated environmental protection, the aim is to devise a process that causes as little pollution of air, water, and soil as possible, and in which integrated production methods enable residues to be utilized as far as possible. The technical and economic aims of the production process must nevertheless be fulfilled. This definition is also used by the Swiss chemical industry [12].

1.3.2. *Environmental Protection in Research and Development*

Chemical research is the precursor of production. Its aim is to devise solutions to problems that are valid for the long term. The total time required for research, process development, and planning and designing a plant (i.e., until the start of production) is at least six years. New developments must therefore be planned so that even after this time they are still state of the art. Moreover, they are future-oriented only if they take into account the requirements of environmental protection. This means that the environmental protection technology must also be future-oriented and gives extra impetus to developments in the field of environmental protection. Innovation in production methods is therefore an essential precondition for production-integrated environmental protection.

Improvements in environmental protection require capital investment. The introduction of new processes and new production plants always provides an opportunity for further improvement of environmental parameters. Capital investment must therefore be very carefully planned from an environmental point of view. This is ensured by a system of checklists that accompanies a new process from the research stage to the granting of a license by the authorities. At an early stage, in addition to substance data, environmental data are included in evaluation of the process; these are extended as the process is developed stage by stage [13], [14]. In this way, potential environmental problems can be recognized and dealt with at an early stage. The process must be optimized with respect to the amount of residues produced, which should be as low as possible. The possibility of using production methods that lead to smaller quantities of residues or less environmental pollution must therefore be investigated. The result of this investigation can also be abandonment of a project.

Thus, production-based environmental measures are an integral part of research, development, and planning.

1.3.3. *Integrated and Additive Concepts of Environmental Protection*

The environmental demands placed on the production process can be met with the aid of integrated or additive (end-of-the-pipe [15]) concepts.

Production-Integrated Environmental Protection. According to the definition of the VCI (see Production-Integrated Environmental Protection.), integrated environmental protection is production-linked, and that definition is used in this article. Thus, production-integrated environmental protection means measures taken to reduce, prevent, and utilize residues [12], [16-19].

The reduction and prevention of residues can be achieved by

1. Improving the chemical process with the aid of *new synthesis routes*. For example, in the production of aromatic amines, chemical reduction with iron chips is replaced by catalytic reduction by hydrogen.
2. *Shifting the equilibrium*. The use of more favorable reaction conditions can cause the position of the equilibrium to be shifted so that one of the two components A or B is almost 100 % reacted. This can be achieved by using the second component in excess, by removing the product, or by using more favorable temperature or pressure.
3. *Improving selectivity.* A very effective method of reducing the amounts of residues and improving the yield is to increase the selectivity of the chemical reaction. Examples of this include the following:
   - Improvement of the selectivity of catalysts, e.g., by using catalysts that lower the rate of an undesired side reaction
   - Maintenance of high catalytic activity, e.g., by avoiding contact poisons or by developing simple reaction methods
   - Optimization of reaction conditions, e.g., by utilizing differences in the reaction kinetics of the main reaction and the side reaction, more favorable temperature profiles and residence times, or more suitable reactors
   - Recycling of the side product (if the side reaction is reversible)
4. Developing new catalysts, e.g., in production of polypropylene without generation of wastewater using improved

metal – organic catalysts.
5. Process optimization.
6. Changing the reaction medium. If water is replaced by an organic solvent in syntheses, contamination of wastewater can often be drastically reduced. However, environmentally friendly solvent handling involves not only recovery of the solvent from liquid media but also prevention of losses to the atmosphere during storage, transport, production, and subsequent processing. This can be achieved, for example, by adsorptive recovery of solvents from the gas stream.
7. Using raw materials of higher purity.
8. Replacing or eliminating auxiliaries that have a harmful effect on the environment (e.g., chlorinated hydrocarbons).

Gaseous, liquid, or solid residues whose formation during the production process cannot be avoided, even under optimum operation conditions, can often be reused (see. Fig. 1) by methods such as

1. *Internal utilization*, e.g., of the auxiliaries employed in the process, by processing and recycling directly into the process. In the simplest case, the substance can be used directly after separation from the products or process streams (recovery of volatile components of solvents). In other cases, a physical or chemical processing stage is necessary to remove impurities from the recycled components or convert them into a reusable form. Examples include
   - Recovery of sulfuric acid from waste sulfuric acid by concentration or decomposition and reprocessing
   - Recovery of organic solvents from solvent residues, solvent – product mixtures, aqueous solutions, and production residues
   - Thermal decomposition of residues of chlorination processes to give pure hydrochloric acid

2. *External utilization* of the residue, i.e., as a raw material for the manufacture of other products in a separate production plant.

Figure 1. Approaches to environmental protection in chemical production

Reutilization of residues by linking of production processes is not another form of residue disposal, but enables resources to be used as economically as possible. However, this does lead to additional interdependencies, which may decrease flexibility.

Additive Environmental Protection. If the technical and economic possibilities for prevent-ing, avoiding, or reusing residues (as part of a production-integrated environmental protection program) are exhausted, additive environmental technologies must be used:

1. Disposal of waste by land-filling and incineration
2. Techniques for purifying waste gas and wastewater

Of course, not all problems of environmental protection in the chemical industry can be solved by new process concepts based on the principles of prevention and utilization of residues. In many cases, additive processes are still necessary.

In the past, the main emphasis was on additive environmental protection employing conventional purification and disposal methods. Nevertheless, methods of recovery and utilization have long been used in the chemical industry, and can even be found at the beginning of industrial production [19].

In the chemical industry a long tradition exists of reprocessing reaction mixtures (e.g., by solvent extraction or distillation), with recovering of auxiliaries (e.g., organic solvents), and recycling these into the production process (internal recycling). For example, a desired product that is dissolved in a solvent following an extraction process can be recovered only by distilling off the extraction agent. This yields the solvent in a pure form that can be recycled, and such recycling is an inherent part of the production process. It is also a “prevention” (in the sense of the German Federal Pollution Control Act, Bundesimmissionsschutzgesetz) since the residues remain in the production plant [20]. Changes in the production process aimed at increasing the yield or reducing the generation of residues have always been tasks of chemical research. Nevertheless, the technology of integrated environmental protection is becoming increasingly important because current requirements with respect to the prevention and utilization of residues are much more stringent than ever before.

Product-Integrated Environmental Protection. The concept of *product*-integrated environmental protection should be distinguished from that of *production*-integrated environmental protection. The former includes the utilization of product waste (e.g., the recycling of plastics, ⟶ Plastics, Recycling) and the development of environmentally friendly products. These measures are also part of an overall environmental protection strategy of the chemical industry [21]. They form a separate subject that is not discussed here.

1.3.4. *Comparison of Integrated and Additive Environmental Protection*

In additive environmental protection, harmful substances formed in a production process are disposed of at a later stage. There is no saving of raw material; instead, residues are converted into a comparatively environmentally harmless form by the use of additional raw materials and energy.

Additive techniques represent unproductive capital [22]. Moreover, these techniques do not reduce the consumption of raw materials. *Integrated techniques* reduce the consumption of raw materials and the production of waste [23]. However, new integrated techniques can lead to higher energy consumption. Integrated techniques sometimes offer economic advantages, whereas additive techniques with linear emission reduction lead to increased marginal costs or greatly decreased marginal utility [24]. This is shown for three German chemical companies taken as examples. Here, the use of additive environmental protection gave an increase in operating costs (Fig. 2), a reduction of emissions into the atmosphere (Fig. 3) and residual contamination of wastewater (Fig. 4). The extent of purification currently achieved in wastewater treatment plants cannot be improved significantly even at greater expense. The residual contamination of wastewater can be reduced only by techniques of integrated environmental protection. A similar development can also be seen in the case of waste from chemical production (⟶ Waste – Integrated Measures to Reduce Environmental Burdens). The slight reduction in operating costs for environmental protection observed in 1992 and 1993 shows that integrated techniques are to some extent beginning to have an economic effect. However, if the operating costs of environmental protection are expressed as a percentage of value added, a further increase is observed (Fig. 5).

Figure 4. Residual contamination of wastewater determined by COD

A) Hoechst; B) Bayer; C) BASF

Figure 5. Operating costs of environmental protection in relation to added value

A) Hoechst; B) BASF

In contrast to additive technologies, the costs for operating and managing the new process are sometimes greater in the case of integrated techniques [25], [26]. Additive techniques are widely available and well proven or can be developed and installed in ca. two to four years. Integrated techniques, however, require research, development, and the approval of licensing authorities, which can take six to ten (or even more) years before they are incorporated into the production process [27], since the entire process must often be designed afresh. Administrative barriers of environmental licensing authorities may also hinder the introduction of complex and innovative integrated techniques [22]. On the other hand, additive technologies for the disposal of materials, such as land-filling and waste incineration plants can meet resistance from the public.

1.4. Limitations of Production-Integrated Environmental Protection

1.4.1. *Technical Limitations*

The technology for improving a process by avoiding or reducing residues is not always available. Each process must be researched and developed individually. Additional fundamental knowledge of chemical processes must be acquired, which requires time and money. Even so, the production of residues cannot be prevented completely. The idea of a production process with 100 % yield, i.e., with “zero emission of hazardous materials of any kind [28],” is a vision that can never exist in reality [14], [29].

Also, the utilization of residues (e.g., contaminated solvents or solvent mixtures) may be limited for technical or economic reasons. Some practical examples of this are given below.

Volatile Organic Compounds in Poly (Ethylene Terephthalate) Synthesis [30]. In the production of poly(ethylene terephthalate), PETP, low boiling organics are produced during solvent processing. These consist of a mixture of methanol, methyl esters of aliphatic carboxylic acids, and cyclic ethers. No internal or external method of reusing this material could be found. A process was investigated for hydrolyzing the methyl esters and recovering the methanol.

Waste-Gas Purification by Scrubbing with Glycol Ethers [16]. In the pharmaceutical industry, certain waste-gas streams are purified by scrubbing with glycol ethers. The solvent mixture produced on desorption contains ca. 16 components that are impossible to separate.

Complex Solvent Mixtures [31]. Problems preventing the separation of complex solvent mixtures are summarized below:

1. The azeotropic behavior of solvent mixtures (e.g., methyl acetate – acetone – methanol) can prevent distillative separation
2. The thermal instability of substances dissolved in a solvent mixture can also prevent distillative separation
3. Solvent residues are needed for dissolving partially polymerized organic residues to produce a material of suitable consistency for pumping into an incinerator

1.4.2. *Economic Limitations*

Investment decisions for new production plants or changes in production methods cannot be made without taking into account the existing market situation and the question of future demand for the product.

The quality and profitability of a product must be ensured under given market conditions. In principle, a new production process can be put into practice only if the costs, including the costs of residue disposal, are less than those of the existing process [32-34]. For any investment decision [35],

$$C_{\mathrm{INT}} < C_{\mathrm{ST}} + C_{\mathrm{EOP}}$$

where C_{INT} are the total costs of the new integrated technology; C_{ST} the costs of the standard technology; and C_{EOP} the costs of retrofitting with the additive environmental technology.

If the existing production plant has not yet reached the end of its economic life, the total costs C_{INT} must also include the sunk- cost.

Economic considerations can also limit the utilization of residues. An example is given in the following: In the proposed manufacture of a pharmaceutical product (capital cost: 1.28×10^6 €, ca. \$ 1.6×10^6), a mixture of ethanol, triethylamine, and water is produced. Investigations aimed at producing the ethanol and triethylamine in a purity suitable for utilization showed that recovery of the ethanol and triethylamine would require a special distillation plant consisting of two specially designed columns and a special storage to comply with German regulations for flammable liquids. The capital cost of this plant would be 3.4×10^6 DM (ca. \$ 2.25×10^6). The costs of the recovered solvents would be greater by a factor of 2.8 than the cost of new ethanol and triethylamine plus incineration of the residue mixture in the internal waste incineration plant. The solvent mixture was therefore disposed of by incineration [31].

1.5. Effect of Production-Integrated Environmental Protection

The effect of production-integrated environmental protection is represented by the amounts of residues prevented or utilized. These are compared with the amounts of residues not utilized — i.e., waste products. Figures have been provided by BASF, Bayer, and Hoechst. These are given below:

BASF [36]. In 1987, 750 000 t of residues were utilized in chemical production. Of this, 380 000 t were used for the manufacture of products. The amount of material recycled within a process is considerable (e.g., recycling of raw material not reacted on passing through the reactor or recycling of auxiliaries such as solvents). The quantities certainly exceed the quantities of products sold (1987: 8.3×10^6 t). The quantity of residues utilized by outside companies in 1987 was 110 000 t. These included mainly the following:

1. Calcium carbonate from water treatment and fertilizer manufacture was used as a raw material in the cement and limestone industry
2. Plastic waste was sold to external consumers
3. Chlorinated hydrocarbons were used in the production of hydrochloric acid or as raw materials in the synthesis of perchlorinated alkanes
4. BASF has a waste materials exchange system involving the internal or external supply or sale of byproducts, superseded products, etc.

In the same year, the amount of waste produced was 897 000 t.

Bayer [37]. In the Bayer works, ca. 1.2×10^6 t of production residues were utilized in 1989. Of this material, 80 % was utilized directly, 15 % was recycled to the production operation after chemical conversion, and 5 % was burned to produce energy. The residues were of the following types: waste sulfuric acid 38 %, hydrochloric and other mineral acids 30 %, inorganic residues 15 %, miscellaneous residues 12 %, and flammable residues for energy production 5 %. The amount of waste produced in the same year was 875 000 t.

These figures for BASF and Bayer do not include internally recycled solvents. Therefore, they cannot be compared with the figures given for Hoechst below.

Hoechst [38]. In the Hoechst group in Germany, without special recovery techniques ca. 3.45×10^6 t of potential waste or residues would have been produced in manufacturing operations in 1992. By the introduction of new processes or the improvement of existing processes in earlier years, the formation of ca. 300 000 t of residues and waste materials was prevented. A further 2.68×10^6 t were recycled and utilized, and ca. 470 000 t of residues had to be disposed of as waste. Thus, the fraction of the total residues that were utilized was 85 % (in the solvent residue area: ca. 95 % [30]), and 15 % was disposed of as waste.

The most important residue groups are listed below, together with the recycled amounts in tonnes:

Aliphatic and aromatic solvents by redistillation	779 085
Hydrochloric acid (31 %) by distillative processing	400 746
Hydrochloric acid (100 %) from vinyl chloride production used for oxychlorination	132 600
Chlorinated hydrocarbons by distillation	188 747
Energy-rich residues used as substitute fuels	38 510
Hydrochloric acid (31 %) from incineration of chlorination residues	57 750
Sulfuric acid by distillation reprocessing or as supply to other users	62 534
Carbon disulfide from waste gas	12 320
Na_2SO_4 and $(NH_4)_2SO_4$ from wastewater and spinning baths	106 330
Recovery of acetic acid and acetaldehyde	56 067
Aromatic and aliphatic hydrocarbons	87 791
Activated carbon and carbon residues	86 210
Catalysts and inorganic substances	34 758

1.6. Costs of Integrated Measures

Capital investment in integrated environmental protection as a percentage of total investment for environmental protection is considered by economic experts to be an indicator of the quality of the environmental protection (EP) or an indicator of preventive environmental protection. The following statements have been made based on this indicator [39-42]: A “quantity – quality trade-off ” occurs in the industry.

1. That means that a relative increase in the quantity of capital investment for end-of-pipe instead of production-integrated measures leads to a reduction in the overall quality of environmental protection
2. Capital investment into end-of-pipe technologies does not satisfy the precautionary measures preferred by environmental policy
3. Political support for end-of-pipe measures is short-sighted

All these conclusions are based on an interpretation of data from the Statistisches Bundesamt zur Grundstoff- und Produktionsgüterindustrie (German Federal Bureau of Statistics for the Basic Raw Materials and Capital Goods Industries). This interpretation is as follows [39-42]:

1. Integrated EP capital investment expressed as a percentage of total EP capital investment is ca. 20 %
2. Most capital investment is in end-of-the-pipe and not in integrated technology

However, the figure of 20 % has not been proved for the chemical industry. By using the author's data, the proportion of integrated EP investment in the chemical industry is calculated to be ca. 6 %, but the data cannot be verified in practice.

Several authors [43-45] agree with the above statements. However, these cannot be confirmed because annual statistics from the German Bureau of Statistics do not distinguish between additive and integrated measures [8]. Thus, sufficiently accurate information on such protective measures cannot be obtained from the statistics. This also applies to the proportion of integrated technologies in the total environmental protection capital investments for the Federal Republic of Germany, which was estimated to be 18 % in 1984 [9], [46].

At present, no method exists for calculating the size of capital and operating costs for production-integrated environmental measures. The assessment also fails for new products made by new environmentally-sound processes.

Therefore, figures for integrated EP capital investment and resulting operating costs are not yet available. They are contained in the overall amounts of capital investment and operating costs of the production process. Moreover, the reduction in residues and emissions is a much better indicator of successful environmental protection than the amount of capital hypothetically invested [29].

2. Examples of Production-Integrated Environmental Protection in the Chemical Industry

Jürgen Wiesner, Claus Christ, Wolfgang Führer, Horst Behre, Hubertus Cuppen, Michael Lumm, Franz-Josef Mais, Gerhard Schroeder, Ferdinand Senge, Dieter Stockburger, Ludwig Schmidhammer, Gregor Lohrengel, Lothar Kerker, Hans Regner, Ulrich Rothe, Volkmar Jordan,

Bernhard Gutsche, Thomas Glarner, Konrad Stolzenberg, Jörg Talbiersky, Cornelis van Os, Christopher Higman, Roberto De Piaggi, Motohisa Miyachi, Fumihiko Oda, Jun Yonamoto, Günther Schumacher, Wilhelm Tischer

2.1. Introduction

The following examples from the international chemical industry illustrate the concept of production-integrated environmental protection described in Chapter Production-Integrated Environmental Protection in the Chemical Industry. Other publications and company monographs show that the total number of examples of this type in chemistry is actually much larger [12], [17], [18], [30], [31], [47-50].

However, the uneven distribution of these examples with respect to countries shows that so far not all nations place equal emphasis on production-integrated environmental protection in the chemical industry. This observation may be due to the following factors:

1. Differences in legal requirements limiting emissions and residues from production processes
2. The intensity of research required for production-integrated process improvements
3. The close association between production-integrated measures and investment decisions on new production plants or essential modification of processes
4. The usually higher degree of complexity of production-integrated methods compared to conventional processes with additive environmental protection
5. The dependence on the quality of raw materials available when certain components or impurities associated with the raw materials are decisive for emission and residue problems
6. The influence of the operation mode: continuous processes being simpler to optimize than batch processes

The examples given here can be classified in accordance with one or more of the following principles:

1. Prevention or reduction of emissions and residues by modification or optimization of chemical syntheses:
   - Development and use of novel and more selective catalysts Examples: 2.2.2.1, 2.2.2.3, 2.2.7, 2.2.10
   - “Biocatalysis”Examples: 2.2.1.9, 2.2.14.1, 2.2.14.2
   - Kinetic optimization of process conditions Examples: 2.2.5.2, 2.2.7, 2.2.8
   - Increase of product yield by shifting of the equilibrium and product recycling Examples: 2.2.1.7, 2.2.2.2, 2.2.5.1, 2.2.7
   - Nonaqueous synthesis route Examples: 2.2.1.3, 2.2.2.1 (intermediate product), 2.2.10
   - Low-residue digestion of raw material Example: 2.2.6
   - Prevention of byproducts by avoiding associated substances in the raw materials Examples: 2.2.5.2
   - Change to continuous operation Examples: 2.2.1.8, 2.2.2.1, 2.2.7

2. Prevention of emissions by optimized operation techniques
   - Low-emission vacuum technique Example: 2.2.1.5
   - New methods of product separation and purification Examples: 2.2.2.2, 2.2.2.5, 2.2.13

3. Process-integrated recycling of auxiliaries and byproducts Examples: 2.2.1.1, 2.2.1.2, 2.2.1.8, 2.2.2.4
4. Recovery of raw materials or auxiliaries for the production process by reprocessing of residues Examples: 2.2.1.4, 2.2.1.6, 2.2.2.4, 2.2.12, 2.2.13
5. Utilization of residues and coupled products by linking of production processes Examples: 2.2.1.1, 2.2.1.4, 2.2.1.6, 2.2.4, 2.2.11
6. Energy saving and prevention of emissions due to burning of fossil fuels by utilization of process energy, recovery of energy from residues, and higher process efficiency Examples: 2.2.1.3, 2.2.1.8, 2.2.1.9, 2.2.2.6, 2.2.3.1, 2.2.5.2, 2.2.7, 2.2.8, 2.2.9, 2.2.10, 2.2.11, 2.2.14.1, 2.2.14.2

2.2. Selected Examples

2.2.1. *Examples from Hoechst*

2.2.1.1. *Recovery and Utilization of Residues in the Production of Viscose Staple Fiber*

General Features of Viscose Staple Fiber Production (⟶ Cellulose – Viscose Fibers) [51]. Cellulose from wood is the most important starting material for staple fiber production by the viscose process. Cellulose xanthate is obtained by converting cellulose to sodium cellulose followed by treatment with carbon disulfide.

Reaction scheme

1. Production of alkali cellulose
   Cellulose + NaOH ⟶ Alkali cellulose
2. Aging
3. Viscose formation (dissolution of alkali cellulose by addition of carbon disulfide)

$$\text{Alkali cellulose} + CS_2 \rightarrow \text{Cell-O-}\underset{\underset{\text{SNa}}{|}}{\text{C}}\text{=S}$$

Side reaction:

$$2\,CS_2 + 6\,NaOH \rightarrow Na_2CS_3 + Na_2CO_3 + 3\,H_2O + Na_2S$$

4. Ripening
5. Regeneration of cellulose fibers in the H_2SO_4 – Na_2SO_4 – $ZnSO_4$ coagulation bath

$$\text{Cell} - O - CS_2Na + NaHSO_4 \rightarrow Na_2SO_4 + CS_2 + \text{Regenerated cellulose}$$

Side reactions :

$$Na_2CS_3 + H_2SO_4 \rightarrow Na_2SO_4 + H_2S + CS_2$$

$$Na_2S + H_2SO_4 \rightarrow Na_2SO_4 + H_2S$$

$$Na_2CO_3 + H_2SO_4 \rightarrow Na_2SO_4 + H_2O + CO_2$$

Cellulose xanthate is dissolved in aqueous sodium hydroxide solution to give a viscous liquid — the viscose. The sodium hydroxide solu-tion, which is added in excess, also results in the formation of byproducts such as sodium trithiocarbonate and sodium sulfide. In addition sodium carbonate is formed.

The ripening of viscose is stopped after a certain time, depending on the nature of the required end product, and the cellulose is precipitated. This is performed by injecting the filtered spinning solution through fine nozzles (the orifices of the spinneret) into an acid bath. The main reaction occurring in the acid bath is the coagulation of viscose, and CS_2 is formed. In side reactions, salts formed in the preparation of the spinning bath decompose to H_2S, CO_2, and Na_2SO_4 (step 5).

As the strand or slubbing is led out of the spinning bath, subsequent degassing occurs, in which carbon disulfide and hydrogen sulfide dissolved in the acid spinning bath partly evaporate. The spun fibers then pass through several aftertreatment baths. In the course of this, adhering sulfuric acid is washed off. A subsequent degassing of carbon disulfide and hydrogen sulfide also occurs in the wash baths, which are mostly hot.

For production of 1 t of staple fiber, up to 350 kg of CS_2 is required. About 25 % of the CS_2 decomposes to H_2S and CO_2. The schematic of the entire process is shown in Figure 6.

Figure 6. Schematic of viscose staple fiber production

a) Mashing; b) Ripening; c) Sulfidization; d) Dissolving; e) Filtration; f) Spinning; g) Stretching; h) Cutting; i) Washing and aftertreatment; j) Drying; k) Transport; l) CS_2 recovery

The Problem. During the production of staple fibers by the viscose process, toxic *waste gases* containing carbon disulfide and hydrogen sulfide are formed. In the conventional process, those waste-gas streams that contain mainly carbon disulfide were collected in a waste-gas system with associated recovery. These waste gases arise during deaeration and exhaustion in viscose production and during aftertreatment of the viscose staple tow. In the recovery plant, after the separation of the hydrogen sulfide fraction, carbon disulfide was adsorbed on activated carbon. Up to about 65 % of the carbon disulfide used was recovered.

The greater part of the other sulfur-containing waste gases — ca. 60 – 90 kg of sulfur in the form of CS_2 and H_2S per tonne of staple fiber — previously entered the waste air. This part originated mainly from the spinning process and also from the spinning bath components discharged with the fibers, from which the gases are released by diffusion in the later treatment stages. In the original procedure, the waste-gas sources in the process had to be exhausted with very large quantities of air to keep waste-gas concentrations safely below the in-plant threshold limit. The specific quantity of waste gas was therefore extraordinarily high (ca. 235 000 m^3/h at an output of 55 000 t of viscose staple fiber per year). The extracted gases, greatly diluted, reached the open air via a tall stack. As a result, nuisance odors often occurred in the surroundings of viscose staple fiber plants because the threshold odor concentration of hydrogen sulfide, at ca. 0.005 mg/m^3, is extraordinarily low. Disposal of the waste gas failed because of its large volume and low concentration.

Considerable quantities of *sodium sulfate* and *zinc sulfate* are also formed during regeneration of cellulose fibers. Part of the sodium and zinc sulfates is discharged from the spinning bath together with the viscose fibers and enters the wastewater through the aftertreatment of the fibers.

Solution [51-54]. To solve the waste-gas problem, a recycling scheme was developed by Hoechst and Süd-Chemie, Kelheim/Germany, and realized in 1975 – 1979. In this process, 80 % of the viscose waste gases were collected. In the following years, further increase of collection to 90 % was achieved, and the waste-gas volume was simultaneously reduced considerably. In the recycling scheme, sulfur-containing waste gases from viscose staple fiber production (Hoechst) are supplied to a neighboring sulfuric acid plant (Süd-Chemie) where they are used as a raw material or as

combustion air. The sulfur compounds contained in the waste gases are combusted to SO_2, CO_2, and H_2O, and the SO_2 is processed to H_2SO_4. The sulfuric acid produced can be used again directly for the coagulation bath. The new process concept required substantial changes and new developments in both plants. In addition it provided the preconditions for improved recovery of carbon disulfide in the viscose plant.

New Concept of Waste-Gas Capture during Viscose Staple Fiber Production. As a result of the basic chemical reactions in a sulfuric acid plant and the desired conversion of nearly 100 %, the ratio of the quantity of combustion air to sulfur is fixed. If the entire amount of waste gas formed in a conventional viscose staple fiber plant were to be used as combustion air in a sulfuric acid plant, about 30 times as much sulfuric acid would have to be produced as the staple fiber plant consumes. The quantity of lean waste gas from the viscose plant must therefore first be matched to the much lower combustion air requirement of the sulfuric acid plant. This can be achieved by appropriate reduction of the air exhaustion in the viscose staple fiber plant. However, this is possible only if, at the same time, risks to safety as a result of exceeding the in-plant threshold limit value and of the occurrence of explosive gas – air mixtures are avoided.

For this purpose, waste gases from the various process stages are assembled in two separate systems: waste-gas system 1 (“rich gas”) is used for the collection of combustible but not explosive gases (waste-gas concentration >explosive range), and waste-gas system 2 (“lean gas”) is used for the collection of waste gases of low concentration (waste-gas concentration <explosive range). Extensive changes to the viscose staple fiber plant were necessary to minimize waste-gas emission:

1. The quantity of carbon disulfide required in viscose production was reduced by developing a special aging process.
2. Because of the new concept of collection of waste air from viscose production, the spinning machines, stretching and tow washing, and subsequent waste-air treatment, most of the carbon disulfide can be recovered from the waste gas.
3. To recover hydrogen sulfide from the spent spinning bath acids as completely and at as high a concentration as possible, a vacuum degassing plant was constructed. The concentrated waste-gas stream of ca. 200 m^3/h can be utilized directly in the sulfuric acid plant (rich gas).
4. By careful enclosure of the spinning machines and the apparatus in the acid station and by using novel exhaustion systems, the total waste-air stream of 180 000 m^3/h (STP) has been reduced to 10 000 m^3/h (STP). The entire spinning machine waste air can therefore be routed via the waste-gas purification plant (CS_2, H_2S). Lean gas from the acid station is used as combustion air in the sulfuric acid plant.
5. Finally, an extensive waste-air collection and piping system had to be constructed. Corrosion problems in the lines had to be ruled out by selecting suitable materials.
6. To ensure safety, a series of additional measures was required: e.g., a largely flangeless construction and reduced-pressure mode of operation of the waste-gas system to avoid leaks; installation of a process measuring and control technology with emphasis on safety; and construction of an additional exhaustion system on the spinning machines for manual operating procedures.

Hydrogen Sulfide Recovery. Waste air from the production installations (spinning, stretching, tow washing), which is contaminated with CS_2 and H_2S, is freed from H_2S by a multistage wash with sodium hydroxide solution (Fig. 7, a). In the course of this, an NaSH-containing spent lye is formed. Subsequently, CS_2 contained in the waste gas is adsorbed on activated carbon (b) and then desorbed with steam (Supersorbon process). The desorbate water –CS_2 vapor is precondensed at 60 °C (c). The gaseous residue is then condensed at 15 °C, and the condensate is drained off into the separator (e). The aqueous phase obtained, together with the precondensate, is stripped of CS_2 in a column (d). The CS_2 is returned to the production process.

Figure 7. Carbon disulfide recovery in viscose staple fiber production

a) Wash column; b) Adsorption on activated carbon; c) Condenser; d) CS_2 stripper; e) Separator; f) Zinc precipitation; g) Acidification (H_2S used for H_2SO_4 production)

Zinc Recovery. Part of the spent lye from the gas wash (a) is used to precipitate zinc (f) from the stretching bath and from the wastewater of the tow wash. By addition of H_2SO_4 to the precipitated zinc sulfide, zinc sulfate is recovered for the spinning process. During zinc precipitation, a small portion of zinc polysulfide is formed that cannot be converted to zinc sulfate. This portion must be discharged.

Hydrogen Sulfide Utilization. The H_2S content of the remaining spent lye (g) is released by adding H_2SO_4 and utilized in the neighboring sulfuric acid plant together with H_2S from zinc sulfate recovery and waste gas (CS_2, H_2S) from the spinning bath regeneration.

Sodium Sulfate Recovery. In the spinning bath regeneration, the spinning bath is partially evaporated. In the course of this, sodium sulfate is obtained in a marketable form by crystallization. The overall flow sheet of the new process is shown in Figure 8 A.

B) Overall balance of the integrated pollution control solution

Supplementary Engineering Equipment for Process Rearrangement. To be able to utilize the lean gas stream, which is saturated with water vapor, in the sulfuric acid plant, a new wet –dry catalytic process for sulfur combustion was developed jointly by Süd-Chemie and Lurgi. In this process the water vapor from the SO_3 – SO_2 gas mixture is removed after the third catalytic stage by condensation in a new absorption process. The dry SO_3 – SO_2 gas mixture then passes through the fourth catalytic stage. Depending on the degree of dilution of the waste gases (with N_2 and CO_2 as inert constituents), the new process gives a sulfuric acid yield of 99.1 – 99.4 %.

Pollution Control Balance. The overall balance of the integrated pollution control is shown in Figure 8 B. As a result of collecting the waste-air streams, ca. 90 % of the original emissions of sulfur compounds from the plant can be avoided, corresponding to ca. 5000 t/a (calculated as S). Only the waste air arising during manual operations on the spinning machines, which is greatly diluted as a result of the additional exhaustion, must be discharged from the stack as before. Apart from rare plant upsets, the nuisance odor in the surroundings of the plant is a thing of the past.

Moreover, during spinning bath regeneration, about 40 000 t/a of anhydrous sodium sulfate is recovered. This corresponds to about one-half of the amount formed in the overall viscose process (including neutralization steps). The remaining wastewater enters a Biohochreactor (⟶ Biochemical Engineering) for degradation of the organic materials (dissolved cellulose ingredients).

The solution found here to the viscose waste-gas problem dispenses with additional energy requirement in the form of electric power, fuel gas, or natural gas. No new waste materials are produced. The operating costs of the process depend basically on the market price of sulfuric acid. The process scheme has by now been applied internationally in several viscose plants.

2.2.1.2. *Recovery of Methanol and Acetic Acid in Poly(Vinyl Alcohol) Production [16], [55]*

In the production of poly(vinyl alcohol) (Mowiol; ⟶ Polyvinyl Compounds, Others – Poly(Vinyl Alcohol)), a mother liquor containing methanol and methyl acetate is produced. This mother liquor is converted to acetic acid and methanol in a multistage process; these substances are then recycled to the production process.

In the first stage, the mother liquor is subjected to distillation. An azeotropic mixture of methanol and methyl acetate is obtained as overhead product. The methanol – water mixture, which remains in the distillation bottom, is fed to a second distillation stage, and the methanol distilled off is recycled to the production process.

The azeotropic mixture is subjected to an extractive distillation (extraction medium: wastewater from the methanol distillation). The still bottoms so obtained, a water – methanol mixture, are fed to the methanol distillation. Methyl acetate taken from the top of the column is fed to a reactor where it is hydrolyzed to methanol and acetic acid with the aid of an ion-exchange resin. In the subsequent distillation, acetic acid is removed, and the mixture of methanol and unreacted methyl acetate from the extractive distillation is recycled (Fig. 9). Wastewater from this recovery process is treated in a biological wastewater treatment plant.

Figure 9. Recovery of methanol and acetic acid

a) Distillation; b) Scrubber; c) Extractive distillation; d) Hydrolysis reactor

2.2.1.3. *Acetylation without Contamination of Wastewater [56]*

The acetylation of 2-naphthylamine-8-sulfonic acid was formerly carried out in an aqueous medium with acetic anhydride. The product, 2-acetaminonaphthalene-8-sulfonic acid, was salted out from the aqueous medium by addition of ammonium sulfate and filtered off.

The mother liquor together with the washwater from this filtration contained 1200 kg of ammonium sulfate (COD 1000 kg) for each 1000 kg of product. This wastewater was treated in a biological wastewater treatment plant (see Figs. 10 and 11). The formation of this highly contaminated wastewater was the reason for replacement of the process by dry acetylation. For this, a flat-bottomed vessel with stirring equipment was installed (Fig. 12, a). Because of the dry process, no contaminated wastewater was formed; thus, treatment of ca. 2000 kg of sewage sludge in the wastewater treatment plant was avoided. In addition, 270 kg of acetic acid was recovered per 1000 kg of product.

2.2.1.4. *Reutilization Plant for Organohalogen Compounds*

Introduction. Organic halogen compounds, especially those containing bromine and fluorine, are intermediates in the synthesis of pharmaceuticals, plant-protection agents, special high-performance plastics, and liquid crystals for optical displays. These intermediates must be produced in highly pure state. They are therefore separated from byproducts formed during the chemical synthesis in later purification stages.

Since the byproducts are often not directly reutilizable, they are disposed of in a waste incineration plant. Up to now only a recovery of the energy content is possible; a chemical reutilization of the byproducts is not. Purification of the flue gas does not lead to reutilizable sustances.

The objective was not only to utilize the calorific values of these byproducts or residues but also to reuse them chemically. This was achieved by thermal oxidation (incineration) with simultaneous neutralization to give potassium halides that are subsequently dissolved in water. The salt solution obtained is used for the recovery of potassium bromide, potassium fluoride, and potassium chloride as raw materials.

Method of Operation (Fig. 13). Liquid organic residues, which contain mainly bromine compounds with some chlorine and fluorine compounds, are fed through jets into a vertical cylindrical oxidation chamber (incinerator, a). The essential feature of the oxidation chamber is a special burner system that causes intensive turbulence of liquid and gaseous residues, fuel, and combustion air. An auxiliary flame produced by a special burner fired with natural gas is necessary to establish and ensure continuous operation of the oxidation process. This burner produces a very intensely radiating flame that reduces the mixing zone within the oxidation chamber. Intensive mixing of the gases ensures complete reaction, which results in comparatively low emissions of NO_x and CO. The high calorific value of the organohalogen residues ensures that the thermal energy necessary for the process is liberated.

Figure 13. Recovery of bromine from residues containing brominated organics

a) Incineration and salt production (1200 °C); b) Quench cooling (85 °C); c) Scrubber (two stages); d) Electrostatic filter; e) Scrubber (one stage); f) Stack; g) Filtration; h) Bromine recovery; i) Evaporation

Waste air from the production of halogenated aromatics is used to form part of the combustion air, so that the residues present in the waste air (e.g., fluorine compounds) can also be treated in the recovery process.

The residues are converted to hydrogen halides in the oxidation chamber at 1200 °C and a residence time of at least 2 s. The hydrogen halides are then immediately neutralized by the simultaneous spraying of potassium hydroxide solution into the chamber, to form potassium halides. This prevents the formation of free hydrogen halides or of elementary halogens according to the Deacon equation. In the case of bromine, the equation

$$2\,Br_2 + 2\,H_2O \rightleftharpoons 4\,HBr + O_2$$

is shifted completely to the right by immediate neutralization of the hydrobromic acid. The equilibrium reaction is then no longer reversible, and complete conversion of the residues to hydrogen halides and, ultimately, potassium halides occurs.

This also avoids the secondary reaction

$$Br_2 + 2\,KOH \rightleftharpoons KBr + KBrO + H_2O$$

which occurs if the potassium hydroxide solution is added to the waste gas at a later stage, as in conventional exhaust-gas purification.

The potassium salts that are liquid at >800 °C flow partially down the walls to the bottom of the oxidation chamber and are dissolved in the water bath in the quenching vessel (b) directly below. The vapor-phase fraction of the salt forms aerosols

in the quenching vessel on cooling to ca. 85 °C. The concentrations of these aerosols are then reduced in the multistage waste-gas purification equipment (c – e) to levels below the limit values stipulated by Regulation 17 of the German Federal Antipollution Law (17. Verordnung Bundesimmissionsschutzgesetz 17. BImSchG). In this equipment, waste gas is passed successively through two jet scrubbers (c), a condensation electrostatic filter (d), and a packed column fed with H_2O_2 (e).

The liquid level in the quenching vessel is kept constant by adding liquor from the waste-gas scrubbers. Thereby some evaporation of the salt solution occurs.

Insoluble components of the salt liquor (ca. 1 % of the residues treated) are removed by filtration. These components consist mainly of insoluble inorganic salts and metal oxides; they can be dumped or, preferably, reutilized.

Elementary bromine is obtained from the filtered salt solution by reaction with chlorine in a further process step. Potassium chloride and potassium fluoride are recovered by evaporation of the remaining solution (with heat recovery from the quenching vessel) and are internally recycled.

The purified waste gas (see above) then undergoes a final purification by passing through a two-stage waste-gas scrubber in a production plant for inorganics (see Fig. 13).

Advantages of the Process. The formation of dioxins is prevented by the high oxidation temperature (1200 °C), the residence time of 2 s in the reactor, the mainly homogeneous temperature profile in the oxidation chamber, and the quench cooling of the reaction gases from 1200 to 85 °C. Measured concentrations are <0.1 ng/m^3 toxicity equivalents dioxins and furans.

Known alternative methods for treating liquid residues either have disadvantages or offer no advantages:

1. *Hydrogenation process*
   The high fluorine content of the residues leads to problems with construction materials. Elementary bromine is not recovered. Production of the hydrogen required for the process is energy intensive.
2. *Plasma process*
   Since the plasma burner can be used only as a pre-stage before the subsequent oxidation with air or pure oxygen, the consumption of electrical energy, and the cost of the plant are excessively high. Further recovery of the halogens will be similar to that used in the recommended process. The ecological balance of this process is therefore very unfavorable.
3. *Pressure gasification*
   A mixture of CO, CO_2, and hydrogen halides is formed at ca. 1600 °C. The hydrogen halides must be separated by waste-gas purification to recover the halogens. The formation of elementary bromine in the gasification process is problematic and would lead to considerable difficulties in waste-gas purification.
4. *Chemical reverser*
   In a converter tube clad with a special ceramic, a reductive atmosphere with a hydrogen excess at very high temperature is produced by combustion of propane under pressure. The fluid organohalogen compounds are decomposed in this temperature region.

For the substances mentioned above containing high levels of aromatics, the mixture would have to be led through a combustion chamber before entering the reactor to convert the molecules into suitable fragments that are able to react with hydrogen in the cracking process.

The later process steps, such as quenching and gas purification, would be very similar to those in the process initially described. It would be complicated to include the use of waste air as combustion air or the use of heat of reaction in the concept of the chemical reverser.

2.2.1.5. *Vacuum Technology for Closed Production Cycles*

In a chemical production plant, a large number of different machines, fittings, and safety equipment must work together reliably. With suitable engineering design, the amount of residues can be reduced or the residues can be recovered.

In the chemical industry, many processes are operated at reduced pressure (between 2000 Pa and atmospheric pressure). Liquid ring pumps, which are displacement pumps, are widely used for pressure reduction (⟶ Vacuum Technology – Displacement Pumps). The working liquid of a liquid ring pump must perform the functions of a piston, a seal, and a heat absorber.

This working liquid can be water or an organic liquid. Water ring pumps are used in recycling operations to reduce wastewater contamination. If a gas at higher temperature saturated with a solvent is pumped, the same solvent can be used as the working liquid of the pump. In a recycling operation, such a system can be designed for solvent recovery by connecting it to a rectification column. An example of this system is shown in Figure 14, in which isopropanol is the solvent.

Figure 14. Vacuum plant with liquid ring pump

a) Liquid ring pump; b) Separator; c) Waste-gas condenser; d) Rectification; e) Cooler for working liquid (isopropanol); f) Condenser

Such a system cannot be used for pumping solvent mixtures or low-boiling solvents (e.g., acetone). Nor can water ring

pumps be used because these lead to contamination of the wastewater. Here, sliding vane rotary vacuum pumps (without oil lubrication) can be used (⟶ Vacuum Technology – Sliding Vane Rotary, Rotary Plunger, Rotary Piston Pumps, ⟶ Vacuum Technology – Rotary Lobe Vacuum Pumps). Such a vacuum pump has been developed for pumping solvent mixtures produced during synthetic resin production. It has been put into operation by Herberts in association with the company Provac (see Fig. 15). The following plant design was used: The vapors are drawn under reduced pressure through the precondenser (b) to the Roots vacuum pump (c). The gases that have been heated by compression in the Roots vacuum pump are then cooled in the intermediate condenser (d), and the condensate formed is automatically removed via a condensate trap into a collection vessel (g). The gases leaving the intermediate condenser are fed into two sliding vane rotary vacuum pumps (e) arranged in parallel. The gases from these pumps are fed into a condenser (f) in which more condensate is formed; this also drains into the collection vessel. The residual vapors are then fed to the waste-gas purification system. This method of operation reduces contamination of the wastewater, and a mixture of solvents is recovered. Furthermore, the inclusion of a Roots vacuum pump eliminates the use of a steam ejector pump, thereby avoiding the contamination of wastewater that such a pump would cause.

2.2.1.6. *Utilization of Exhaust Gases and Liquid Residues of Chlorination Processes for Production of Clean Hydrochloric Acid*

When organic compounds are chlorinated on an industrial scale, large quantities of hydrogen chloride are formed. This is contaminated with chlorinated hydrocarbons formed as byproducts of the chlorination process.

A measure of the degree of contamination is given by the content of halogen compounds that can be adsorbed from the acid by activated carbon (AOX content). In nearly all chlorination reactions the chlorine is incompletely consumed, so that a fluctuating proportion of free chlorine usually occurs both in the hydrochloric acid recovered from the residual gases from the chlorination process and in the waste gases.

This free chlorine is as undesirable as other impurities in both the waste gas and the hydrochloric acid, and must be removed for environmental reasons and to improve acid quality.

One method of producing cleaner hydrochloric acid and a waste gas with only traces of organic impurities is to subject the chlorinated residues to thermal treatment before the absorption stage. In this treatment, the impure, hydrogen-chloride-containing gases are heated in suitable combustion chambers to ca. 600 – 1200 °C. The energy is usually provided by the combustion of natural gas or other fuels in an excess of oxygen, the temperature being adjusted to suit the impurities present. The flue gases obtained contain low levels of organic substances as well as some free chlorine. The latter occurs because in the presence of oxygen, free chlorine originally present in the chlorination residues does not react quantitatively to form HCl according to the equation

$$2\,Cl_2 + 2\,H_2O \rightarrow 4\,HCl + O_2$$

Instead, additional free chlorine can even be formed.

In subsequent absorption of the hydrogen chloride, free chlorine partly dissolves in the hydrochloric acid formed and partly remains in the waste gas. Removal of chlorine from both the hydrochloric acid and the waste gas is technically difficult. Air blowing or stripping the hydrochloric acid gives incomplete removal of the chlorine and causes a considerable decrease in the concentration of the acid.

Moreover, additional chlorine-containing and hydrogen-chloride-containing waste-gas streams are formed, and these too must be purified. Like the dechlorination of the original waste gases, this can in principle be performed only by alkaline scrubbing, which transforms the waste-gas problem into a wastewater problem.

A method for removing hydrogen chloride and chlorine from combustion gases with recovery of hydrochloric acid in a multistage gas scrubbing process has been described [57].

In another process for reducing the free chlorine content of flue gases from a combustion plant [58], hydrogen is fed into the quench zone of the combustion apparatus at a rate that depends on the air rate to the combustion chamber. By this means, the chlorine content of a combustion gas has been reduced from 600 to 48 mg/m^3. However, chlorine-free waste gases have not yet been produced from flue gases with such high chlorine contents.

Finally, a process has been developed for disintegrating chlorinated hydrocarbon residues with recovery of hydrochloric acid [59]. The chlorine content in the flue gas from the combustion process is kept as low as possible by minimizing the oxygen content and feeding steam or water into the combustion chamber. However, the hydrochloric acid produced is apparently not completely free of elementary chlorine, because chlorine is sometimes still found in the waste gas after HCl absorption.

Methods are also described for the combustion of liquid and solid residues with the production of hydrochloric acid [60], [61]. In these processes also, the starting material is burned in an excess of oxygen, as already described. Thus, these methods have the same disadvantages as those mentioned, because chlorine is present both in the hydrochloric acid produced and in the waste gas.

A method has been developed for producing hydrochloric acid with low levels of AOX and almost no elementary chlorine, together with a waste gas that contains only traces of these substances and can be released directly into the atmosphere. Here, the hydrogen chloride and chlorine-containing crude gases contaminated with organic compounds are thermally treated by using hydrogen or hydrogen-containing combustion gases with a deficiency of oxygen. The fuel and air rates are adjusted so that no carbon is formed in the combustion zone and an excess of hydrogen is present in the exhaust gas [62].

Although this process enables chlorination residues of the usual composition to be purified so that they can be used to produce pure hydrochloric acid, in extreme cases (e.g., if very high levels of impurities are present in the crude gases or if liquids are to be treated), problems with carbon formation in the combustion chamber can arise. This is undesirable, because both the plant and the products would be fouled.

Novel Process [63], [64] (Fig. 16). A thermal process was needed in which the reaction would proceed in a stable and controllable fashion. This process would also have to be suitable for purifying both crude gases with extremely high levels of impurities and chlorine-containing liquids. These could be converted to hydrogen chloride so that the latter could be directly absorbed without further purification processes, to give chlorine-free hydrochloric acid and a waste gas suitable for immediate discharge to the atmosphere.

Figure 16. Production of pure hydrochloric acid from residual chlorination gases and liquid chlorination residues

a) Evaporator; b) Two-stage combustion; c) Quench; d) Isothermic absorber; e) Adiabatic absorber

The problem was solved by using thermal treatment of the impurities in a combustion operation with an excess of oxygen, and by following the first combustion stage by a second in which reaction gases from the first stage are subjected to further thermal treatment, in this case in a reducing atmosphere.

The crude gas mixture to be treated contains, in addition to hydrogen chloride and chlorine, considerable quantities of chlorinated hydrocarbons and other organic chlorine compounds. The mixture is subjected to a *two-stage thermal treatment*. It is fed into a *first combustion chamber* supplied with sufficient fuel and air. (Under some circumstances, replacing the combustion air either completely or partially with oxygen can be advantageous in this stage of the combustion process.)

Gaseous fuel (e.g., natural gas or hydrogen) is generally used in the first combustion stage, although liquefied petroleum gas or light or heavy fuel oil can also be used. In the *second combustion stage*, fuels with the lowest possible carbon content are preferred, because carbon formation is more likely here than in the first combustion stage since the process requires a deficit of oxygen.

If high-carbon fuels are used in the first combustion chamber, or if the raw gas contains large quantities of compounds with a high carbon content, the substoichiometric reaction in the second combustion chamber can lead to the formation of large amounts of carbon monoxide according to

$$CO_2 + H_2 \rightarrow CO + H_2O$$

After HCl absorption, the waste gas cannot be discharged directly because of legal restrictions. In this case, CO in the waste gas is converted to carbon dioxide, preferably in an afterburner under controlled conditions or sometimes catalytically.

The combustion chambers generally consist of steel vessels lined with a refractory ceramic material. Since this lining is not usually gastight, the highly corrosive raw gases, which contain hydrogen chloride and especially chlorine, can corrode the interior walls of the steel vessels at the prevailing surface temperatures, so that metallic ions, especially iron ions, appear in the hydrochloric acid formed. If high-purity hydrochloric acid is required (i.e., a product that not only is free of elementary chlorine and organic compounds but also contains only traces of inorganic compounds such as metallic salts, especially iron chlorides), the interior walls of the steel vessels and combustion chambers should be given a corrosion-resistant coating (e.g., enamel) before application of the porous ceramic material.

The crude gas to be treated is fed into the first combustion chamber. If necessary, liquids can first be passed through a vaporizer, and the vapors produced can then be mixed into the rest of the crude gases. If the liquids have high boiling points, feeding steam into the vaporizer can be useful. Combustion can be improved by adding combustion air, fuel, and additional steam or chlorine gas to increase the HCl content of the reaction gases.

The combustion temperature in the first chamber can be 800 – 1600 °C (preferably 1000 –1300 °C); this is maintained by an auxiliary burner. The fuel – air mixture is adjusted so that an oxygen content of 0.1 – 11 vol % (preferably 0.5 – 5 vol %) is measured in the reaction gases at the exit of the first combustion chamber.

The reaction gases pass from the first to the second combustion chamber. There the temperature is maintained at 800 – 1600 °C (preferably 1000 – 1300 °C) by a burner supplied with a fuel –air mixture whose ratio is adjusted so that the reaction gases at the exit of the combustion chamber have a hydrogen content of 1 – 15 vol % (preferably 2 – 5 vol %).

Sometimes, the temperature of the second combustion chamber may have to be decreased by feeding steam into this chamber.

The reaction gases are passed through one or more absorption columns after cooling.

Preferably the pressure in the first combustion chamber should be kept constant automatically by a blower installed downstream.

The hydrochloric acid produced is practically free of elementary chlorine and organic chlorine compounds, and requires no further treatment. Also, the purified gas can be discharged directly into the atmosphere.

2.2.1.7. *Production of Neopentyl Glycol: Higher Yield by Internal Recycling [38], [65], [66]*

In the process for producing neopentyl glycol (2,2-dimethyl-1,3-propanediol) a coupled product is formed and some starting materials remain unreacted (⟶ Alcohols, Polyhydric – 2,2-Dimethyl-1,3-propanediol (Neopentyl Glycol)). The latter are internally recycled to the process with the aid of the coupled products.

The first reaction, in reactor 1, is an aldol condensation in which formaldehyde is reacted with isobutyraldehyde (2-methylpropanal) in an alkaline medium with tri-*n*-propylamine as the catalyst to form hydroxypivalaldehyde (3-hydroxy-2,2-dimethylpropanal).

The reaction mixture is transferred to a separating vessel where two layers are formed. The organic phase contains hydroxypivalaldehyde and an equilibrium amount of isobutyraldehyde. The heavier aqueous phase contains hydroxypivalaldehyde together with small amounts of unreacted starting materials (formaldehyde and isobutyraldehyde). The organic phase is hydro-genated in reactor 2 using a nickel contact catalyst. Here, the target product neopentyl glycol is formed from the hydroxypivalaldehyde and, isobutanol is formed from the isobutyraldehyde as the coupled product.

Neopentyl glycol and isobutanol are separated by distillation. Some of the recovered isobutanol is used to extract the aqueous phase formed in the aldol condensation, and the remainder is used to produce synthesis gas. The isobutanol extract contains hydroxypivalaldehyde and starting materials. It is therefore recycled to the aldol condensation reactor. The isobutanol transferred into reactor 1 then enters reactor 2 via the organic phase. This leads to an increase in the amount of isobutanol so that, after separation by distillation, some of the isobutanol can be used to produce synthesis gas. Wastewater from the bottom of the extraction column is fractionated. The low-boiling compounds formed as overhead products are also used to produce synthesis gas (Fig. 17). Wastewater from the fractionating column is treated in the biological wastewater treatment plant.

2.2.1.8. *Optimization of Ester Waxoil Production and Recovery of Auxiliary Products [16], [67]*

Ester waxoils are produced from crude montan wax by oxidation with chromic acid to acid waxes, followed by esterification with aliphatic polyalcohols. The products are used in polishes for automobiles and furniture.

The crude montan wax contains resinous components that are removed by methylene chloride treatment. The methylene chloride is then recovered by distillation of the solution obtained (Fig. 18). In detail, the process consists of mixing the crude wax with methylene chloride (a) and filtering the mixture through a band filter (b). The CH_2Cl_2 is recovered from the filtrate (resin dissolved in CH_2Cl_2) with the aid of a recirculating evaporator (d), separating vessel (i), and condenser (e) and the residual resin can be incinerated (f). The deresinified crude wax is melted (c) and is stripped with steam to remove any remaining CH_2Cl_2 (h).

Figure 18. Methylene chloride recovery in wax production

A) a) Mixing vessel; b) Filter unit; c) Melting vessel; d) Evaporator; e) Condenser; f) Separating vessel; g) Activated carbon filter; h) Stripping column; i) Separator; j) Resin incineration; k) Receiver; l) Stripping column

B) Mixing vessel (a) in detail: Continuous wax oxidation

The subsequent oxidation process with chromic acid is optimized. The earlier batchwise process in lead-lined stirred vessels resulted in contamination of water, and the consumption of raw materials and energy was high. This has now been replaced by a continuous process in which montan wax and a chromic acid – sulfuric acid mixture are passed through a sieve tray column. The two components are intensively mixed by compressed air as they enter the column (Fig. 19, a), giving a high conversion of chromic acid. The exothermic reaction heats the mixture to the temperature required, so that external heating of the column is unnecessary. This procedure gives an oxidation product of uniform quality, leads to savings in energy and raw materials, and enables the purification stage to be performed continuously and effectively. The steam saving is 1 t per tonne of wax acid compared with the previous process. The consumption of chromic acid is reduced from 170 % of the crude montan wax (former process) to 115 %. The consumption of electricity for regeneration of the exhausted chromic acid, [i.e., for electrolytic oxidation (i) of chromium(III) to chromium(VI)] is reduced by 2000 kW · h per tonne of acid wax.

Figure 19. Chromium circulation at the oxidation stage of wax production

a) Continuous oxidation column; b) Separating vessel; c) Flotation; d) Oxidation tower; e, f) Mixing tanks; g) Filter press; h) Mixing tank; i) Electrolysis

DCW = Deresinified crude wax; BWTP = Biological wastewater treatment plant

The exhausted chromic acid [chromium(III) salt solution] produced in the oxidation stage is separated from the acid wax by phase separation (b) and flotation processes (c) and is electrolytically treated (i). The anolyte [chromium(VI) salt] is fed into the oxidation column (a). The catholyte [chromium(III) – chromium(II) salt mixture] is partly fed into an oxidation tower (d) and partly mixed with wastewater (spray and wash water), which contains chromium(VI). This causes the chromium(II) present in the catholyte to be oxidized and the chromium(VI) in the wastewater to be reduced. In both cases, a solution of chromium(III) is formed. The small amount of chromium in the wastewater is precipitated as chromium(III) hydroxide by addition of sodium hydroxide solution (f), and then filtered off in a filter press (g) and brought into solution in the acid conditions in the mixing tank (h). This is followed by the electrolytic oxidation stage to form chromic acid (i). Residual wax from the flotation stage is oxidized later in a separate operation.

Separation of chromic acid residues from the oxidation product is carried out continuously today by a disk separator. Zirconium is the only construction material that can be considered in view of the highly corrosive properties of the medium. A disk separator of zirconium has been developed specifically for this purpose in cooperation with an engineering company. This gives both an improvement in product quality by reducing the chromium content of the oxidation product and a saving of sulfuric acid for the washing processes. The sodium sulfate content of the wastewater is thus reduced by 13 kg per tonne of acid wax.

2.2.1.9. *Biochemical Production of 7-Aminocephalosporanic Acid [68-70]*

Introduction. 7-Aminocephalosporanic acid (7-ACS) is a pharmaceutical chemical obtained by elimination of α-aminoadipic acid from the fermentation product cephalosporin C. 7-Aminocephalosporanic acid is the key product for most semisynthetic cephalosporin antibiotics. It is used by Hoechst to produce Claforan (cefotaxime sodium), cefodizime, Cefquinom, and Cefpirom. Until now, 7-ACS has been produced by a chemical process. A process based on biochemical catalysts has now been developed and is considerably more environmentally friendly.

Chemical Process. The chemical process used hitherto consists of the following stages:

1. Production of the zinc salt of cephalosporin C
2. Reaction of the cephalosporin C zinc salt with trimethylchlorosilane to protect the functional groups (NH_2 and COOH)
3. Productions of the imide chloride from the silylated product by reaction with phosphorus pentachloride at 0 °C
4. Hydrolysis of the imide chloride (see Fig. 20) to yield 7-ACS.

Figure 20. Production of 7-aminocephalosporanic acid

Enzymatic Process. The enzymatic synthesis is carried out as a two-stage process:

1. Cephalosporin C is supplied directly to the enzymatic stage. The side chain of the molecule is oxidatively deaminated by a D-amino acid oxidase (obtained from yeast). Oxygen is consumed, and ketoadipinyl-7-ACS, ammonia, and hydrogen peroxide are formed. Under these reaction conditions, oxidative decarboxylation to form glutaryl-7-ACS occurs spontaneously.
2. In the second stage of the process, the glutaric acid is split off by the enzyme glutaryl amidase, and 7-ACS is liberated (see Fig. 20).

The reactions are carried out at room temperature in aqueous solution. The enzymes are immobilized on a spherical carrier and can be reused many times. The enzyme D-amino acid oxidase is obtained in good yield from the natural host bacterial strain.

In the production of the enzyme glutaryl amidase, only a low concentration was produced by the wild strain *Pseudomonas.* An economically interesting concentration (greater than fiftyfold increase per volume unit) can be produced only by genetic engineering (i.e., cloning the enzyme glutaryl amidase in *Escherichia coli*).

Comparison of the two Processes. The chemical process is inferior to the enzymatic process with respect to the reactants and auxiliaries employed:

1. Use of chlorinated hydrocarbons and toxic auxiliaries
2. Use of phosphorus pentachloride, which is subject to the German decree about emergencies (Störfallverordnung), and of trimethylchlorosilane, which can be handled only in the absence of moisture and is highly flammable
3. Use of heavy-metal salts (i.e., zinc salts)

Use of the enzymatic process leads to the following changes in the amounts of residues produced (per tonne of 7-ACS) compared with the chemical process:

1. Mother liquors requiring incineration: reduction from 29 to 0.3 t
2. Waste-gas emissions: reduction from 7.5 to 1.0 kg
3. Wastewater contamination (COD): increase from 0.1 to 1.7 t
4. Residual zinc by recovery as $Zn(NH_4)PO_4$ and reutilization: reduction from 1.8 to 0 t
5. Distillation residues (from the distillative treatment of the chlorinated hydrocarbons) for incineration as waste: reduction from 2 to 0 t

Furthermore, the chemical process is energy intensive, since it can be carried out only at low temperature.

The fraction of the process costs used for environmental protection is reduced from 21 to 1 %. This fraction includes the cost of the additive environmental protection (waste incineration and purification of wastewater and waste gas). Thus, the absolute environmental protection costs are reduced by 90 % per tonne of 7-ACS.

2.2.2. *Examples from Bayer*

2.2.2.1. *Avoidance of Wastewater and Residues in the Production of H Acid (1-Amino-8-hydroxynaphthalene-3,6-disulfonic acid)*

Introduction. Development of the so-called coal tar dye industry has resulted in extensive knowledge of naphthalene chemistry. The “letter acids” based on naphthalene derivatives are very important, especially for azo dyes. The color properties of the chromophore present depend highly on the substitution pattern of the naphthalene nucleus. The introduction of sulfonate, nitro, amino, and hydroxyl groups in various positions is therefore an important characteristic feature of the production of these intermediates ($\longrightarrow$).

A dye component that is used frequently is H acid (1-amino-8-hydroxynaphthalene-3,6-disulfonic acid). Production of this comparatively complex substitution pattern requires a series of different chemical reactions. The known side reactions and subsequent reactions on sulfonation and nitration of the naphthalene system and high-pressure hydrolysis of its substituents reduce the yield of the target product. If, as a consequence, intermediate isolations are unavoidable during the course of the process to prevent a gradual increase in the amount of byproducts, additional product losses in mother and wash liquors will occur. Management of the often considerable quantities of solid waste and wastewater is therefore an important consideration in the production of H acid.

Conventional Process. The production process for H acid is divided into four basic operations each of which includes several steps:

1. Sulfonation of naphthalene to give the trisubstituted product
2. Nitration of the trisulfonic acid
3. Reduction of the nitro group to T acid
4. High-pressure hydrolysis of the sulfonic acid group in the α-position to give H acid

This long reaction chain was distributed over various buildings of the Leverkusen works.

The rule of ARMSTRONG and WYNNE applies to the multiple sulfonation of naphthalene; i.e., the two sulfonic acid groups that enter the ring are in neither the ortho, the para, nor the peri position to each other [71]. Therefore, no further reaction to form naphthalenetetrasulfonic acid occurs after the desired 1,3,6-substitution. However, this pattern can be obtained only via the 1,6- or 2,7-disulfonic acid as intermediates. The desired yield is therefore influenced considerably at the very beginning of the reaction by the selectivity and completeness of the reaction forming the disulfonic acid intermediate stage. A considerable proportion of the naphthalene used is lost at the sulfonation stage according to [72].

The sulfonation product is then nitrated. Reaction conditions can be chosen such that the α-position is preferred [73]. The directing effect of the sulfonic acid groups promotes substitution at the desired position. However, nitration of the naphthalene nucleus has a much greater tendency to lead to side reactions (e.g., oxidations) than is the case with the benzene series, so that when the nitrated mixture is diluted with water, nitrous gases are evolved.

The acid solution is neutralized by adding calcium carbonate, and the precipitated gypsum produced from the excess sulfuric acid is filtered off. The nitrated product remains in the filtrate and is reduced by iron chippings to T acid (1-aminonaphthalene-3,6,8-trisulfonic acid). The remaining calcium ions are removed as calcium carbonate together with the iron oxide by adding sodium carbonate solution, (⟶) and the T acid is isolated as an intermediate by acidification of the filtrate, so that the various byproducts can be removed with the mother liquor.

Naphthalenesulfonic acids are hydrolyzed to hydroxy derivatives under drastic alkaline conditions, and sulfonic acid groups in the α-position react preferentially [74]. Thus, the T acid is converted to H acid by treatment with sodium hydroxide solution under pressure [75]. The H acid is then salted out with sodium chloride. Because of the unfavorable solubility properties, large quantities of sodium chloride must be employed which remain in the mother liquor with the organic byproducts.

In view of the yields of individual stages quoted in the literature, even after many years of production experience, this process gives an overall yield of only 40 % based on naphthalene.

Revised H Acid Process. The poor infrastructure (various stages of the process carried out at different locations), age of the plants, and intensity of emissions, among other factors, have provided the motivation to attempt a systematic revision of the process. This has led to complete redesign of the operation in the factory at Brunsbüttel [76], [77]. Operation in Brunsbüttel began in 1981, and the old plants have been completely replaced.

The basic process pattern is unchanged. The important changes to the process are replacement of several intermediate steps by a continuous system, and replacement of iron reduction by hydrogenation with hydrogen using a nickel catalyst [78]. A modern process control system is used that considerably reduces variation of the process control parameters compared with the earlier in situ manually controlled system. Salting out and isolation of intermediates (e.g., T acid) are omitted. There is now only the isolation of the target product. Waste-air and wastewater emissions that still occur are purified in new plants. Those waste-gas streams from the plant that contain nitrogen oxides, organic compounds, and hydrogen are treated in a combustion plant. The remaining wastewater stream containing organic byproducts from the synthesis that are difficult to degrade biologically is reacted in a wet oxidation plant with oxygen at high pressure. This “wet incineration” proceeds almost to completion, so that subsequent biological wastewater purification is unnecessary.

Ecological Aspects of the Process. In comparison to the earlier process, the modern H acid production process shows considerable improvements in emission levels for equal quantities of the target product.

Results of the revision of the process

1) Starting materials

Naphthalene	– 20 %
Sulfuric acid	– 20 %

Calcium carbonate	– 20 %
Nitric acid	– 20 %
2) Gypsum	– 38 %
3) Iron oxide sludge	–100 %
4) Volume of wastewater	– 70 %
5) Wastewater load	
Sodium chloride	–100 %
COD	– 96 %
Sodium sulfate	+ 12 %

Efficiency. Consumption of the raw materials naphthalene, sulfuric acid in various concentrations, nitric acid, and calcium carbonate is now 20 % lower.

Gypsum and Calcium Carbonate Sludge. Because of their improved quality, gypsum and calcium carbonate sludge are no longer dumped, but are supplied to the cement industry for use as raw materials. Also, the quantity of gypsum produced has been reduced by 38 %.

Iron Oxide Sludge. Attempts were made to utilize the iron oxide sludge produced in the reduction by iron chippings of the nitrated compound to T acid. Use of this sludge as a raw material for the production of iron oxide pigment or in iron smelting was not very successful, so it was disposed of mainly by dumping. The present hydrogenation process produces only water as the byproduct. Catalyst recovered from the process is reutilized.

Volume of Wastewater. The omission of intermediate isolation stages, the change to continuous operation of various intermediate reaction stages, and the introduction of an intermediate evaporation stage led to a reduction by 70 % in the amount of process wastewater that must be treated because of its organic content.

Organic Load of Wastewater (*COD*). The aqueous processing steps, which are the rule in letter acid production, lead to the presence of side products formed from naphthalene in the process wastewater. The biological wastewater treatment is regularly unable to eliminate these materials (elimination rate sometimes <20 % within normal holding periods) satisfactorily.

The efficiency of conversion of raw materials is now considerably improved, and amounts of unavoidable byproducts have been reduced by high-pressure wet oxidation, so that the COD is now reduced by ≥96 %. Wastewater can therefore now be discharged directly into the Elbe.

Salt Content of Wastewater. Because of the considerably smaller amounts of water used in the process, the former technique of isolating H acid by salting out could be omitted. The process no longer requires the addition of sodium chloride, so 4.7 t of sodium chloride per tonne of H acid is no longer used. However, the increase in sodium sulfate content of 12 % (i.e., a total of 3.8 t per tonne of H acid) has to be accepted, but nonetheless the salt load of the wastewater is considerably reduced.

Economic Constraints. The example described is an illustration of the opportunities afforded by modern process technology to improve a production process that has remained the same in principle for 100 years. However, notwithstanding the process improvements achieved, the cost of the new plant and installations presents an increasing problem when viewed against the background of prices in international competition. Especially in Asia, obsolete technology and the associated increase in environmental pollution are tolerated. This results in cost structures that have consequences for the world market when they are widely used to confer market advantages.

The example therefore raises the question to what extent production-integrated environmental protection is hindered by lack of international harmonization. Environmental protection measures require a long-term positive outlook with respect to both market forecasts and official regulations, because the time scales for systematic process modernization, licensing, new plant construction, and an appropriate initial operating phase for refinancing must be taken into account.

2.2.2.2. *High-Yield Production of Alkanesulfonates by Means of Membrane Technology [79], [80]*

Introduction. Alkanesulfonates are anionic surfactants (⟶ Surfactants – Alkanesulfonates). They are produced by Bayer through the sulfochlorination process. Optimum properties are obtained when a mixture of straight-chain alkanes with 14 – 17 carbon atoms is used.

The alkanesulfonyl chloride (Mersol) produced by the sulfochlorination reaction is hydrolyzed with sodium hydroxide solution to give the sodium sulfonate. The hydrolyzed mixture separates on cooling into a product-rich upper phase (“glue”) and a salt-containing lower phase that still contains ca. 2 – 3 % sulfonate and must be disposed of.

Conventional Method of Recovering the Alkanesulfonates. The reaction product of sulfochlorination (obtained in ca. 30 – 33 % yield) is hydrolyzed at ca. 100 °C with aqueous sodium hydroxide, and the mixture obtained is cooled in several stages. Most of the unreacted alkanes separate in the hot phase and are recycled to the production process. The aqueous hydrolyzed solution contains residual alkanes, alkanesulfonates, and sodium chloride produced from reaction of the sulfonylchloride with sodium hydroxide solution.

On cooling to ca. 6 °C, an aqueous phase separates, which contains ca. 2 – 3 % of alkanesulfonates, 6 – 7 % sodium chloride, and traces of alkanes. Further cooling of the lower phase to –6 °C decreases the sulfonate content to ca. 1.5 %.

This lower phase was formerly treated in the central wastewater treatment plant. Apart from salt, it also contains organic substances that give a COD of ca. 20 g/L. Approximately 2.8 m^3 per tonne of sulfonate of the lower phase is produced resulting in a considerable COD in the wastewater.

Membrane Process for Recovery of Alkanesulfonates. Many attempts have been made over the years to reduce the wastewater load — which represents a loss of product — by a number of different methods. These include evaporation, extraction, reverse osmosis, and ultrafiltration. All of these processes have the disadvantage of high equipment cost and high energy requirements, and the space – time yield is low. The first breakthrough came with the development of new types of membrane with a definite separating efficiency and a large surface area, so-called spiral-wound modules.

Nanofiltration is best suited for successful recovery of alkanesulfonates from the lower phase. This process operates with standard spiral-wound modules at moderate pressure and gives recovery efficiencies of ≥90 %.

Suitable nanofiltration membranes based on the spiral-wound module technique are available from various suppliers; they usually consist of a carrier film, a spacer, and the filtration membrane (⟶ Membranes and Membrane Separation Processes – Spiral-Wound Module). After separation, the lower phase is heated preferably to ca. 25 °C, adjusted to a predetermined pH by addition of acid, and pumped at ca. 30 bar through a battery of pressure tubes suitably arranged in parallel and fitted with spiral-wound modules.

The concentrate produced is usually recirculated until the desired concentration is reached and then returned to the production process (e.g., the hydrolysis stage).

The membrane permeate contains <10 % of the initial sulfonate content and is treated in the central biological wastewater treatment plant. The entire process is operated continuously.

Surprisingly, not only do the modules have good retention properties for alkanesulfonates, but the concentrate also contains significantly less salt. The flow sheets for both processes are shown in Figure 21.

Figure 21. Comparison of processes for the production of alkanesulfonates with and without ultrafiltration

Ecological Aspects of the Modified Process. Conventional treatment of the hydrolysis mixture leads to a wastewater stream whose organic load, consisting of lost product and emulsified starting material, is ca. 20 g/L COD. The organic components also contain a certain amount of combined chlorine formed as a result of side reactions with the alkane chains during sulfochlorination.

The introduction of nanofiltration under pressure has led to a reduction in the organic content of the wastewater of up to 95 %, so that the filtrate has a COD of only 0.4 g/L. This decreases the load on the factory's biological sewage treatment plant, especially that due to organically bonded chlorine.

Concluding Comments. Improvement in the efficiency of alkanesulfonate recovery was first made possible by the development of efficient multilayer membranes with long service lives and high retention properties.

A flexible system of switching between modules enables the sulfonate recovery stage to operate for long periods without cleaning or maintenance operations.

The plant was installed in 1992 in the Uerdingen factory and has fulfilled the promise of the early pilot investigations.

2.2.2.3. *Selective Chlorination of Toluene in the para-Position*

Introduction. Monochlorination of toluene — yielding usually a statistical mixture of *ortho*- and *para*-chlorotoluenes — is an important step in the introduction of functional groups into this aromatic hydrocarbon. Monochlorination represents the first stage in a large number of reaction chains leading, for example, to chlorobenzaldehydes or cresols [81]. Applications of such products include plant-protection agents, pharmaceuticals, dyes, antioxidants, and preservatives [82].

Since various product lines follow their own market laws, the demand for *ortho*- and *para*-chlorotoluene fluctuates, *ortho*-chlorotoluene often being the less desired isomer. This situation is a typical problem in coupled production. If it cannot be solved by a pricing policy in accordance with market economics, the only possible solution in the most unfavorable case is to dispose of excess quantities of the less desired isomer (e.g., by incineration).

Conventional Chlorination of Toluene. In the batch chlorination of toluene (e.g., at 50 °C in the presence of $FeCl_3$ catalyst), a crude mixture is formed in which the monochlorotoluene fraction contains small amounts of *meta*-chlorotoluene, with the two isomers *ortho*- and *para*-chlorotoluene in a practically statistical distribution in the ratio *ortho*- : *para*- = 1.92 [83].

Since the economic importance of *para*-chlorotoluene is considerably greater than that of *ortho*-chlorotoluene, catalytic systems have been developed to increase the *para*-selectivity of the chlorination. Since the early 1930s addition of sulfur or disulfur dichloride [84] to $FeCl_3$ as a cocatalyst has been known to shift the isomer ratio in the monochlorotoluene fraction in favor of *para*-chlorotoluene (i.e., to an *o*- : *p*- ratio of 1.11).

Growth of product lines based on *para*-chorotoluene at the end of the 1970s and early 1980s has led to further development of the cocatalyst (⟶ Chlorinated Hydrocarbons). The use of thianthrenes [85-90], phenoxazines [91-93], or phenothiazines [94-97] instead of sulfur is described in patent applications.

However, these methods usually have significant disadvantages; e.g., the quantities of cocatalysts required are too large (0.1 wt % or more), the *o*- : *p*- ratio can be kept only if antimony compounds are used as the main catalyst, or the reaction temperature is too low (20 °C or less) so that the process is uneconomical.

Exceptions to this include the use of a mixture of $FeCl_3$ and polychlorothianthrene [90] or *N*-substituted phenothiazines (e.g., $FeCl_3$ – *N*-chlorocarbonylphenothiazine) [94]. However, these more economical variations achieve at best an *o*- : *p*- ratio of 0.84.

The market tendencies in recent years (e.g., due to new developments and other changes in the plant-protection field) are increasingly incompatible with this isomer distribution. The demand for *para*-chlorotoluene is increasing while at the same time the demand for *ortho*-chlorotoluene remains static or tends to decrease.

New Cocatalysts in Toluene Chlorination. Intensive research into the development of a catalyst system suitable for industrial use has therefore been started. These investigations have resulted in the discovery of the benzothiazepine [98-101] cocatalysts, whose properties are greatly superior to those of former state-of-the-art products. Their *para*-selectivity in comparison with $FeCl_3$ – sulfur (*o*- : *p*- = 1.11) is much increased (up to *o*- : *p*- = 0.55) by using minimum quantities of cocatalyst (e.g., 30 – 50 ppm) in the presence of $FeCl_3$ as the main catalyst and at industrially favorable temperatures of 40 – 50 °C.

After a relatively short optimization phase to establish the exact composition of the catalyst system, the reaction temperature, and the exact flow rates, etc., the new system could be used in an existing continuous full-scale plant.

Hence, in principle, since the early 1990s, the isomeric ratio in toluene chlorination has been adjustable within the range *o*- : *p*- = 1.11 to *o*- : *p*- = 0.55 according to market conditions; i.e., for each tonne of *para*-chlorotoluene produced, the amount of *ortho*-chlorotoluene can be fixed within the range 1.11 to 0.55 t. A comparison of old and new processes is given in Figure 22.

Figure 22. Selective chlorination of toluene in the *para*-position — comparison of old and new process

Ecological Aspects of the Catalyst Change. The decreasing demand for *ortho*-chlorotoluene has limited the possibilities for utilizing the excess material. The effect on cost that would result from incineration of *ortho*-chlorotoluene had to be assessed. With this background, the development of new benzothiazepine cocatalysts relieved the isomer problem at just the right time. The isomer ratio has now been moved in the desired direction and adapted to the demand pattern. No incineration of an undesirable product is necessary.

Concluding Comments. Extensive fundamental research into further development of catalysts has been supported by the use of theoretical chemistry and modern mathematical methods based on random techniques. The plants in which these results have been realized since 1989 operate in the Leverkusen works.

2.2.2.4. *Production of Naphthalenedisulfonic Acid with Closed Recycling of Auxiliaries*

General. Sulfonation of the naphthalene ring system has a long tradition, particularly as an important process step in the synthesis of the numerous “letter acids,” which are important intermediates in dye production. The process parameters (e.g., exclusion of water and temperature control) determine the substitution pattern (positions 1 or 2 in the naphthalene ring system). With an appropriate excess of sulfonating agent, both rings of naphthalene can be substituted, or more highly sulfonated derivatives can be obtained (⟶ Naphthalene Derivatives – Introduction, ⟶ Naphthalene Derivatives – Naphthalenesulfonic Acids). Since undesired isomers and byproducts are formed, sometimes in considerable proportions,

the process steps for workup and product isolation are frequently complex. Product yields relative to the naphthalene used, therefore, turn out to be relatively low.

Conventional Process for Production of Naphthalenedisulfonic Acid. The standard process for sulfonating aromatic hydrocarbons uses sulfuric acid and oleum as reactants. Under these conditions, the reaction vessels can be made out of gray cast iron, and steel can be used for piping and fittings.

$$C_{10}H_8 + 2SO_3 \xrightarrow{H_2SO_4} C_{10}H_8O_6S_2$$

Naphthalene is introduced into sulfuric acid and reacted with added oleum [102]. A temperature of 50 – 60 °C is required for satisfactory space – time yields. The reaction mixture is then added to water in vessels with acid-resistant brick lining. As a result of adding sodium hydroxide solution and sodium sulfate, naphthalenedisulfonic acid precipitates as its disodium salt and can be filtered off. Aside from residual amounts of the target product, considerable proportions of undesired isomeric di- and trisulfonic acid derivatives remain in the filtrate as byproducts. Because of the high saline contamination, a technically satisfactory solution to the problem of obtaining fresh sulfuric acid from these wastewater streams containing sulfuric acid has not yet been found. Likewise, current processes for biological wastewater treatment show only very mediocre elimination performances for this filtrate, so that the effluent of the wastewater treatment plant has high residual organic contamination (see Figs. 23 and 24).

Figure 23. Conventional process for production of naphthalenedisulfonic acid

Figure 24. Mass balance of naphthalenedisulfonic acid production

New Process for Naphthalene Sulfonation. Modification of the process aims simultaneously at two goals: increasing the yield with more selective reaction and recycling sulfuric acid from the wastewater. Accordingly, not only must the parameters of the reaction step be changed so that fewer byproducts are formed, but the product must be isolated by a salt-free alternative process to enable sulfuric acid to be recovered.

The desired higher selectivity of the sulfonation reaction cannot be achieved by using sulfuric acid as a reaction medium but rather by dissolving the reactants, naphthalene and sulfur trioxide, in an organic solvent (chlorinated hydrocarbon, CHC) and reacting them at temperatures lower than those of the previous process [103].

Nevertheless, because of the dehydrating action of sulfur trioxide, higher-molecular structures are formed via anhydride bridges (Scheme 25). The anhydride bridges must, therefore, be hydrolyzed in the next step. For this purpose, the reaction mixture is added to water. An aqueous sulfonic acid solution is formed and the solvent is subsequently separated.

Subsequently, instead of the sodium salt, the free sulfonic acid [104] is precipitated by addition of sulfuric acid or recycled mother liquor, followed by cooling. The mother liquor, which remains after filtering off the product, can be supplied directly to existing plants for regeneration of spent sulfuric acid.

Ecological Aspects of the Process Alteration. The previous process is essentially characterized

Figure 25. Naphthalene sulfonation

by a linear material flow to obtain the target product coupled with a flow of highly contaminated wastewater that contains the high naphthalene losses due to the formation of byproducts, excess sulfuric acid, and inorganic salt. Two recycled streams are now superimposed on this process [105] (see Fig. 26).

Figure 26. New process for the production of naphthalenedisulfonic acid

The organic solvent is recovered for reuse in the production plant. Excess sulfuric acid mother liquor is conveyed via the internal piping system for spent acid to the existing sulfuric acid plant, where concentration, decomposition to sulfur dioxide, and oxidation to sulfur trioxide occur. Sulfur trioxide is then withdrawn and fed to the sulfonation reaction through piping.

In the new process, process wastewater is, therefore, collected as the distillate from spent acid concentration. Since the volatilized components from evaporation are negligible, the previous wastewater contamination of more than 3000 t/a COD, which exhibits rather unsatisfactory biological degradation, is reduced to a few tonnes per year (e.g., from shower, rinsing, or cleaning water). Thus, for this process, a COD reduction of nearly 99.9 % is achieved (see Fig. 24). Simultaneous alteration of the reaction process markedly improves the yield, so that the proportion of naphthalene that does not react to the target product is now reduced by about a half.

Selection of the solvent however, leads, to considerable additional measures in process design and construction engineering. With regard to solvent power, enthalpy of evaporation, phase separation behavior, etc., low-boiling chlorinated hydrocarbons are best. This, for instance, involves special measures for sealing the tank farm on the water side, as well as monitoring the platform and surface drainage with detectors, so that if leaks occur, an emergency tank can be switched in.

The product is crystallized with vacuum cooling. The associated stripping effect allows maximum recycling of the solvent. Because the solvent must be anhydrous for reuse, the collected solvent streams are dried with sulfuric acid in a pulsed column. Waste air collected from the entire apparatus is supplied to a waste-air incineration plant with downstream washers.

Supplementary Engineering Equipment for Process Rearrangement. The conventional process can, in practice, be run manually with on-site operation. In comparison, the additional infrastructure of the new process with its multiple interconnections, as well as accurate maintenance of reaction parameters, requires considerable supplementary installations. Operation of the process is supported by a new control system developed specifically for this purpose. A high degree of standardization and uniform quality is achieved [106]. The new plant has been in operation in Leverkusen since 1989.

2.2.2.5. *Avoiding Residues in Dye Production by Using Membrane Processes [107-112]*

Introduction. In the production of water-soluble dyes, recovery of the product usually occurs by salting out, filtering on filter presses, redissolving or resuspending and refiltering, standardization, and drying. In this process, large quantities of wastewater and salt are produced. With the introduction of the new technique of pressure permeation, the amounts of salt and organic materials produced are reduced considerably, and a higher yield is obtained.

Conventional Process. The end product of many dye syntheses is an aqueous salt-containing dye solution. Separation of the product dye from byproducts such as salts and residual starting materials is performed conventionally by addition of further large quantities of salt to the dye solution to salt out the product dye, which is then filtered off from the salt solution by means of filter presses. Liquor from the presses contains mainly the salts used in the process together with up to 5 % of the product (Fig. 27).

Figure 27. Flow diagrams of the old and new processes for production of a powdered dye

New Process (Fig. 28). An effective new method for reducing wastewater contamination uses pressure permeation. With suitable dyes, the salting-out process and isolation of dyes is replaced by salt removal and concentration of the reaction solution via membranes. The concentrated solution can then be processed further to give a directly marketable product.

Figure 28. Flow diagram of a pressure permeation plant

Pressure permeation plants use semipermeable membranes that are permeable to water, inorganic salts, and small organic molecules, but quantitatively retain dyes in solution. According to the separating characteristics of the membrane and the resulting operating pressures to be used, separation processes are classified as microfiltration, ultrafiltration, nanofiltration, and reverse osmosis. The membrane surfaces are in the shape of spirally wound, plate-shaped, or tubular modules. The salt-containing synthesis solution passes from the reaction vessel into a holding tank and subsequently through the membranes under pressure. There it separates into a salt-containing, almost dye-free permeate, and the dye concentrate. The dye concentrate is recycled to the holding tank. After further treatment, the permeate can be reused as feedwater or otherwise disposed of as wastewater. Compared with the filtrate of the conventional process the permeate produced from the pressure permeation plant has a COD that is decreased by 80 % and a salt content (only reaction salt) decreased by 90 %. The filtration, washing, and redissolving steps, which are complex and labor intensive, are replaced by a fully automatic pressure permeation stage. Since retention of the dye by the membrane is almost quantitative, the dye yield is increased up to 5 % by using the new pressure permeation technique.

Ecological and Economic Aspects of the Process Change. By use of the pressure permeation technique, wastewater contamination can be decreased considerably and thus the following wastewater treatment simplified. Also, the almost complete removal of salts from dyes marketed in the form of highly concentrated solutions virtually eliminates the necessity of adding auxiliaries for standardization.

In addition, the economics are improved by reducing wastewater costs, while product quality remains the same or better, and the yield is sometimes higher. The application of pressure permeation to other fields is being investigated and developed:

1. Extension of the process to other applications (dye grades and intermediate products)
2. Optimization of the synthesis and production processes (Fig. 29)

Figure 29. Residue minimization by pressure permeation

To sum up, introduction of the pressure permeation technique has the following economic advantages: (1) increase in yield, and (2) reduction of wastewater treatment costs; and hence an improved profitability with equal or better product quality.

2.2.2.6. *Fuel Replacement in Sewage Sludge Combustion by Utilization of Chlorinated Hydrocarbon Side Products [113-116]*

Introduction. In the chemical industry, much effort is devoted to preventing residue formation completely. Although great success has been achieved in the area of residue prevention, residue formation cannot be completely avoided in the chemical industry. Attention must therefore be directed toward the most feasible methods of utilizing these residues.

Old Processes. *Production of Sewage Sludge.* In the biological wastewater treatment plants of the Leverkusen works, the organic content is degraded by microorganisms in biological stages. In this process, sewage sludge is formed: first a preliminary sediment by chemical-mechanical purification, and then excess activated sludge from the biological wastewater purification stage.

This sludge has until now been treated by thickening, conditioning, and dewatering, and been disposed of as solid filter cake on the works-owned special waste dumps.

Production of Chlorinated Hydrocarbons (CHC). During the production of, e.g., rubber chemicals, quantities of highly chlorinated hydrocarbons result as byproducts, thus far unavoidably. These materials could not be disposed of at facilities on land and were incinerated in special ships on the high seas.

New Methods. *Incineration of Sewage Sludge.* To dispense with disposal of the organic materials in sewage sludge on the works-owned dump, to minimize the amount of water dumped in the sewage sludge filter cake (which contains 60 % water), and to utilize the available dumping space more efficiently, alternative methods of disposing of the sludge were investigated. The following criteria were formulated for comparing the alternative methods:

1. Volume reduction
2. Process safety
3. Environmental compatibility of the residues
4. Cost

Based on these decision criteria, the method of choice for disposing of sewage sludge was incineration.

Incineration of Chlorinated Hydrocarbons. Finding a way of integrating the incineration of highly chlorinated hydrocarbons into the sludge disposal concept was very important. From the political discussion generated by incineration of these liquid residues on the high seas, one expects only incineration on land to be permitted in the future.

Description of the Process (see Fig. 30). The sewage sludge incineration plant, which has a capacity of 80 000 t/a, is divided into the following sections:

1. Multiple-hearth furnace
2. Afterburner chamber
3. Waste-heat boiler for waste-heat utilization
4. Multistage flue gas purification

Figure 30. Schematic of sludge incineration

a) Sludge bunker; b) Elevator 1; c) CHC storage tank; d) Elevator 2; e) Multideck furnace; f) Ash removal; g) Transport container; h) Boiler feedwater tank; i) Condensate tank; j) Afterburner chamber; k) Waste-gas cooler; l) Quench tank; m) Rotary scrubber; n) Jet scrubber; o) Demister; p) Induction fan; q) Stack

The sewage sludge is conditioned; i.e., filter aids are added to convert it into a form with good filtering properties. The sludge is dewatered in chamber filter presses, stored temporarily in a bunker (a), and charged via trough feeders into the buckets of a transport plant (b, d). These buckets contain ca. 1.5 t of sludge. The sludge is charged by the buckets into a storage vessel on the top deck of the incinerator and is fed continuously from there into the furnace (e). A feed rate of up to 12 t/h sewage sludge can be achieved.

The cylindrical furnace consists of a steel casing with an interior lining and exterior insulation; it is divided into eight horizontal decks. The diameter of the furnace is 8 m, and its height 12 m.

In the center of the furnace is a vertical hollow rotating shaft with four rabble arms for each deck carrying scraper blades arranged at an angle. The rotary motion of the shaft causes the sewage sludge fed to the top deck to be swept from the inside to the outside, and on the next deck from the outside to the inside, falling through openings at the outer and inner edges of the decks to the deck below. The ash, which is produced on the two lowest decks, moves in the same way. The multideck furnace operates in countercurrent; i.e., the combustion air and hot flue gases pass through the furnace in an upward direction, drying the sludge, while the feed material is transported in the opposite direction. Also, the combustion air cools the ash, the air being thereby preheated, and the hot flue gases dry the sludge to be incinerated.

In this method of operation, three different zones are produced in the multideck furnace. From top to bottom, these are

1. Drying zone from deck 1 to deck 4, temperature 400 – 700 °C
2. Incineration zone in decks 5 and 6, temperature 800 – 1000 °C
3. Cooling zone in decks 7 and 8, 250 – 350 °C

At the side of the sixth deck is an uncooled combustion chamber lined with refractory materials. This is used to provide intense heat for starting up the furnace and, if required, can also be used for supplementary heating during incineration of the sludge.

Exhaust gases from the combustion zone and vapors from the drying zone of the multideck furnace pass into a lined afterburner chamber (j). Liquid organic waste (e.g., chlorinated hydrocarbons from production processes) is used as fuel in the afterburning chamber. To avoid chloride corrosion, the outer wall of the afterburner chamber is connected to the recycling system of the process gas cooler and thereby cooled. The completely burned hot waste gas then passes into the waste-gas cooler (k) where its sensible heat energy is used to produce steam. Combustion gases leave the waste-gas cooler at 250 – 300 °C and are then led to flue gas scrubbing. The ash produced is removed via a rotary valve (f) and fed through a chain trough conveyor (g) to the ash removal system of the multiple-hearth furnace for cooling and agglomeration. The ash produced is disposed of on the works-owned dump.

The hot flue gases at ca. 250 °C are cooled to 70 – 80 °C in the quench tank (l) by spraying with water, and the gaseous substances (e.g., hydrogen chloride and hydrogen fluoride) and dust particles are washed out. Any remaining fine dust and hydrochloric acid are removed from the flue gas by a two-stage rotary scrubber (m).

The flue gas is then treated with sodium hydroxide solution in a jet scrubber (n) to remove sulfur dioxide. The purified flue gas passes through a demister (o) and an induced draft fan (p), and into the stack (q).

A comparison of the flow sheets of the old and new processes is given in Figure 31.

Figure 31. Comparison of old and new wastewater sludge treatment and chlorinated-hydrocarbon incineration processes

Outlook. More than 50 % of the sewage sludge produced can now be incinerated. It is expected that all sewage sludge will be disposed of in this way by 1997.

2.2.3. *Examples from BASF*

2.2.3.1. *Emission Reduction in Industrial Power Plants at Chemical Plant Sites by Means of Optimized Cogeneration [117-119]*

Industrial power stations represent some of the largest individual emitters of a number of pollutants from production sites. The most important of these pollutants are CO_2, CO, SO_2, NO_x, and dust.

The 1972 figures for the BASF Ludwigshafen site, which contains more than 300 production plants, are given below:

Total emissions	113 000 t/a
From energy generation	55 000 t/a
From chemical production	58 000 t/a
Individual emissions	
CO	30 000 t/a
NO_x	30 000 t/a
NH_3	2 000 t/a
C_5H_{12}	2 300 t/a
HCl	500 t/a
Dust	6 300 t/a

The primary task of industrial power stations is to generate heat energy for the production processes. On large sites, this heat energy has customarily been produced in power – heat cogeneration plants, so that part of the electrical energy requirement is also produced on-site. These cogeneration plants are mainly steam power plants with characteristic values of 0.15 –0.25 MW · h_{el}/(MW · h_{th}). These characteristic values on the producer side must be compared with those on the consumer side. The following values are typical:

Sites producing their own basic chemicals	0.4 – 0.8 MW · h_{el}/(MW · h_{th})
Other sites	0.25 – 0.35 MW · h_{el}/(MW · h_{th})

Comparison of these figures shows that cogeneration plants using steam-based processes cannot supply the electricity requirements of the consumer on the basis of power – heat cogeneration. On the other hand, small condensation power plants on industrial sites are generally not competitive with the large installations of electricity supply companies. This follows from the decline in capacity of industry-based power stations in West Germany (Fig. 32), which is due entirely to the closure of condensation plants in the industrial area. The shortfall in electrical energy is made up for by purchasing.

Figure 32. Breakdown of industrial electricity generation by prime mover type

a) Back pressure, tapped back pressure, gas turbines, piston engines; b) Condensation machines

Several methods are used to reduce emissions from industrial power stations:

1. Lowering the energy consumption of production plants
2. Removing pollutants from flue gases of industrial power stations
3. Using alternative fuels
4. Using alternative technologies for energy conversion

An economic and ecological optimum is achieved only by a “tailored” combination of all four methods on any individual site.

Lowering Energy Consumption. Attempts to reduce energy consumption of production plants have been very successful in past years. Here, the pinch analysis method of LINNHOFF has proved very effective (⟶).

Pinch analysis is a method of assessing the works infrastructure of production plants and supply systems with respect to energy consumption, quantities of waste products, quantities of emissions, and capital costs. The fundamental elements of pinch analysis are the composite curves, the grid diagram, and the pinch itself.

In the composite curves (Fig. 33), the cold and hot streams of a production plant are plotted against temperature. When the two curves are shifted horizontally relative to each other until the minimum temperature difference necessary for heat-transfer processes is reached at the point where the curves come closest together (pinch), this gives the theoretical minimum for the heat streams that must be supplied or removed (hot and cold utility targets; ⟶ Pinch Technology – Composite Curves and Energy Targets).

Figure 33. Hot and cold composite curves

a) Hot curve; b) Cold curve

The pinch represents the boundary between the balanced heat sources (system below the pinch) and heat sinks (system above the pinch). In the optimum case, no heat transfer occurs across the pinch. The grid diagram (Fig. 34) is used in the development of economical heat recovery systems using the pinch technology.

Figure 34. Grid diagram

The result of systematic assessment of the BASF Ludwigshafen site is shown in Figure 35. The amount of sales products increased by 143 % from 1972 to 1992; however, the factory steam consumption decreased slightly. In 1992, only 33 % of the steam requirement was supplied from primary energy. Whereas the fraction of steam produced by combustion of residues remains the same, the largest fraction today is supplied by the utilization of waste heat from chemical plants. Consequently the consumption of primary energy dropped drastically.

Figure 35. Consumption of primary energy at the Ludwigshafen works

Emission Reduction. The reduction in emissions from power plants was correspondingly drastic, and the more than proportional decrease in the use of the primary energy carrier fuel oil has had an additional effect.

At chemical sites producing sulfuric acid, further reduction in SO_2 emissions of power plants is possible using the Wellman – Lord process (⟶ Sulfur) in which pure SO_2 is recovered and recycled to the production process. The power plant thus supplies starting materials to the chemical production plant, and becomes an integral part of it. In the Wellman – Lord process, SO_2 is absorbed in aqueous sodium sulfite solution with formation of sodium bisulfite:

$$SO_2 + Na_2SO_3 + H_2O \rightarrow 2\,NaHSO_3$$

The SO_2 is then desorbed by heat in a later stage.

Other additive purification processes carried out on exhaust gases led to the decrease in atmospheric emissions at the Ludwigshafen site shown in Figure 36. Emissions of individual components for the year 1992 are shown in Table 1.

Table 1. Atmospheric emissions at the Ludwigshafen site in 1992

	Power plants, t/a	Total, t/a
CO	160	12 500
NO_x	240	6 000
SO_2	1350	2 300
NH_3	0	600
C_5H_{12}	0	100
HCl	26	140
Dust	200	900
Total emission	3500	24 000

Figure 36. Atmospheric emissions from the BASF Ludwigshafen works (excluding CO_2)

a) Total emissions; b) Emissions from power plants; c) Emissions from production plants

Use of Alternative Technologies for Energy Conversion. A new cogeneration technology using natural gas as the energy carrier has also led to a reduction in CO_2 emission. Figure 37 shows the principal arrangements of a conventional steam turbine power plant (A), a gas turbine power plant (B), and a combined gas and steam turbine power plant (C). The range of characteristic values [$MW \cdot h_{el}/(MW \cdot h_{th})$] is also shown in each case. Industrial power stations are fundamentally heat controlled. In a modern cogeneration process using gas turbines in this way ca. three to four times the amount of electrical energy is produced compared with the steam turbine process.

Figure 37. Characteristic values for typical cogeneration processes

A) Combined heating and power stations with steam turbines; B) Combined heating and power stations with gas turbines; C) Combination plant (without supplementary firing); D) Block-type thermal power station with gas engines

So production plants can meet their total demand of electric power and even sell a considerable amount to the public. This also leads to an overall reduction of emissions.

2.2.3.2. *Closed-Cycle Wittig Reaction [120-123]*

The Wittig reaction is widely used in the production of vitamins, carotenoids, pharmaceuticals, and antibiotics. It proceeds, e.g., according to the following scheme:

$$R^1-CH_2-Cl + P(C_6H_5)_3 \rightarrow R^1-CH_2-P^+(C_6H_5)_3Cl^-$$

$$R^1-CH_2-P^+(C_6H_5)_3Cl^- \xrightarrow[-HCl]{Base} R^1-CH=P(C_6H_5)_3$$

$$R^1-CH=P(C_6H_5)_3 + R^2-CHO \rightarrow R^1-CH=CH-R^2 + O=P(C_6H_5)_3$$

The Wittig reaction is characterized by mild reaction conditions and high yields. It therefore meets the criteria for clean (smooth) chemistry. However, its more widespread use is hindered by the fact that equimolar amounts of triphenylphosphine (TPP) must be used, and the inactive triphenylphosphine oxide (TPPO) formed in the reaction is today still disposed of as waste.

The active triphenylphosphine is synthesized according to the overall equation

$$PCl_3 + 3\,C_6H_5Cl + 6\,Na \rightarrow P(C_6H_5)_3 + 6\,NaCl$$

Since TPPO is not easily degraded and phosphorus must not be present in wastewater, the only possible disposal route is as follows (Fig. 38). The TPPO-containing residues are incinerated to form P_2O_5, which is removed in a scrubber with the aid of dilute sodium hydroxide solution. Phosphorus is then precipitated as calcium phosphate and filtered off, and the filter cake is disposed of on a hazardous waste dump. This disposal method has the following disadvantages:

1. The filter cake uses valuable dumping space
2. The P_2O_5 aerosols have a poisoning effect on the DENOX catalysts of the incineration plant
3. The P_2O_5 aerosols cause clogging of cloth filters

Figure 38. Flow sheet for disposal of TPPO

Attempts were therefore made to convert inactive TPPO back to active TPP, which could then be used again in the Wittig

reaction. A route along the following lines was ultimately found to be successful (Fig. 39):

Figure 39. Flow sheet for treatment of TPPO

The TPPO-containing residues are dissolved in chlorobenzene and reacted with phosgene gas to form triphenylphosphine chloride, with liberation of CO_2. In the second step, finely divided aluminum powder is added with mixing. The TPP · $AlCl_3$ complex formed is then decomposed hydrolytically in a third reaction step, giving the desired TPP.

A flow diagram of the process is shown in Figure 40. The TPPO-containing residues from various operations are collected. Residues from other companies can also be included at this point. Pure TPPO is recovered by distillation and dissolved in chlorobenzene.

Figure 40. Schematic of the treatment process of TPPO

Chlorination is carried out in a stirred-tank reactor inside a gastight chamber. Phosgene is also generated in this chamber and fed immediately to the reactor.

Dehalogenation with aluminum powder is carried out in the next stirred-tank reactor.

The TPP · $AlCl_3$ complex is then hydrolytically decomposed with water in another stirred tank in which the pH is adjusted with HCl so that water-soluble $Al(OH)Cl_2$ is formed. The TPP is dissolved in the chlorobenzene layer. Traces of TPP are recovered from the aqueous phase by extraction with chlorobenzene. In a subsequent distillation stage, chlorobenzene is distilled off and recycled. The TPP is then purified by distillation. The aqueous phase from the extraction stage is fed to a sewage treatment plant, which operates in the weakly alkaline range, so that aluminum is precipitated as $Al(OH)_3$ and acts as a flocculation agent in the desired manner.

The ecological advantages of the new process can be seen from a comparison of the ecological balances (see Fig. 41):

Figure 41. Ecological balances of old and new processes

This comparison shows that the new process results in the complete absence of phosphorus emissions, a reduction of the chloride load of the wastewater to one-third of its former value, and a reduction of CO_2 emission to only ca. 5 % of its former value. The new low-emission process for the production of TPP enables the Wittig reaction to be used much more widely in industrial syntheses.

2.2.4. *Integrated Environmental Protection and Energy Saving in the Production of Vinyl Chloride (Example from Wacker Chemie)*

Introduction. The production of vinyl chloride monomer (VCM), starting material for poly(vinyl chloride) (PVC) has a long tradition. Raw materials for VCM production are ethylene, chlorine, air (oxygen), and sometimes external hydrogen chloride (HCl) from other chlorination processes (⟶ Chlorinated Hydrocarbons – Production, ⟶ Chlorinated Hydrocarbons – Vinyl Chloride from Acetylene, ⟶ Chlorinated Hydrocarbons – Vinyl Chloride from 1,2-Dichloroethane). The main production steps are shown in Figure 42. This integrated process contains two internal material cycles, namely, the closed-loop recycling of nonconverted 1,2-dichloroethane (EDC) from the pyrolysis step (so-called recycle EDC) and the closed- or partly open-loop recycling of HCl formed in the cracking step back to the oxychlorination unit. With totally closed-loop recycling of the crack HCl — or if HCl must be exported due to quality reasons or the exported quantity made up by HCl from external sources — the combined VCM process runs “HCl balanced.” However, if crack HCl is exported

without compensation, the combined VCM process becomes “HCl unbalanced.”

Figure 42. Main steps in production of vinyl chloride monomer

Differences in the processes used by individual VCM producers are due mainly to the different technologies applied in direct chlorination; these include high- or low-temperature direct chlorination (both processes are operated in the homogeneous liquid phase in the presence of oxygen as substitution inhibitor), and oxychlorination (fixed- or fluidized-bed process in the heterogeneous gas phase). Differences in these steps determine the energy requirements and the design of equipment for processing and purifying the intermediate products. The latter is as complex as pure product isolation because the reaction products formed in EDC synthesis and EDC cracking consist of multicomponent mixtures.

Conventional Production Process. Figure 43 shows the overall process flow and mass balance of the old process in operation since mid-1976. Target products in addition to VCM are hydrogen chloride for silicon chemistry and 20 % hydrochloric acid for internal site demand. The combined VCM process was nearly “HCl balanced” because the HCl flow exported to silicon chemistry was balanced by imported HCl from a chlorolysis process (tetrachloroethylene production plant). The amount of byproducts was all in all 4.4 wt % related to VCM production. According to JENSEN et al. [124], ca. 64 % of these residues are heavy ends and EDC – VCM tars which were incinerated internally or partly externally (depending on the uptake capacity of the rotary kiln incinerator) with heat recovery but without utilization of their considerable chlorine content. This resulted in a high salt load in the flue gas scrubber effluent. The light ends, ca. 36 % of the total residue amount, were used as secondary raw material for the production of tetrachloroethylene by a perchlorination process. Because this perchlorination process also produced hexachlorobenzene- (HCB) and hexachlorobutadiene- (HCBD) containing wastes — 3600 t of light ends form 345 t of those solid wastes — which had to be disposed at great expense on an underground deposition site, this way of utilizing light ends finally was only a transposed residue recycling without a really closed loop.

Figure 43. VCM production according to the HCl-balanced old process

a) Direct chlorination; b) Acidic wash; c) Recycle EDC chlorination and dechlorination; d) VCM cracking; e) Oxychlorination; f) Acidic and alkaline wash; g) EDC distillation; h) Light ends and H_2O removal; i) Heavy ends and tar removal; j) Chlorination of vent gas from oxychlorination; k) Vent gas incinerator with HCl recovery (Figures are given in 10^3 t/a unless otherwise specified)

The large amounts of toxic vent gases [containing, besides partly cancerogenic chlorohydrocarbons (CHCs), compounds such as carbon monoxide, chlorine, HCl, and hydrocarbons] are produced predominantly during oxychlorination with air. Further emissions are due to various process vent gases and tank breathing. Despite the large gas volume, these vent gases have been treated since 1977 by thermal incineration in an integrated HCl recovery plant (first plant in Europe, Fig. 44) because catalytic incineration, which consumes much less energy, was not practicable due to the high chlorine content of these vent gases (chlorine acts as a strong catalyst poison). Based on the low calorific value of these vents, considerable amounts of natural gas had to be used as auxiliary fuel to guarantee complete carbon combustion at 950 °C and 0.6 – 0.8 s residence time. Most of the waste heat of the flue gas was utilized for the generation of steam at 20 bar by a waste-heat boiler. The mostly organically bonded chlorine in the vents was recovered as 20 % hydrochloric acid in the two-stage flue gas scrubber. To satisfy the site demand of 20 % hydrochloric acid, additional crack HCl had to be introduced into the vent gas incinerator.

Figure 44. Vent gas incineration with HCl recovery

a) Combustion chamber; b) Waste-heat boiler; c) Boiler feedwater preheater; d) Wash column; e) Quenching vessel; f) Demister

Wastewaters produced in the different process stages are (1) reaction water of the oxychlorination process; (2) $FeCl_3$-containing wastewater from the acidic wash decanter of the direct chlorination; (3) slightly alkaline wastewater from azeotropic drying of wet crude EDC in the light ends column; (4) sodium-hypochlorite-containing spent caustic from the flue gas scrubber of the incineration plant; (5) strongly alkaline wastewater from the VCM wash decanter and VCM drying traps; and (6) wastewater from the acidic and alkaline wash decanter of the oxychlorination unit with high COD. Additional surficial wastewater is collected in plant and tank farm pits. This wastewater is more or less strongly contaminated with CHCs. An exception is the spent caustic from the incineration plant. The chlorinated hydrocarbons dissolved in wastewater were recovered by steam stripping and recycled back to the process. Three steam strippers were in operation: one for the surficial wastewater collected in several pits; a second stripper for $FeCl_3$-containing wastewater from the acidic wash decanter of direct chlorination (which has a low COD); and a third stripper (oxy stripper) for acidic reaction water from oxychlorination (which has a high COD), for the COD-rich wastewater from the acidic or alkaline wash decanter of the oxychlorination, for wastewater from the azetropic drying of the wet crude EDC, and for wastewater from the VCM wash decanter and drying traps. The effluents of strippers 1 and 2 were led into a chemical – mechanical sewage treatment

plant ($FeCl_3$ is a desired flocculant in the neutral or slightly alkaline range); the alkaline salt-containing oxy stripper effluent was led into a one-stage biological sewage treatment plant. The effluent from the oxy stripper was still contaminated with a relatively high COD and adsorbable organic halogen (AOX) load.

Besides this high energy-consuming wastewater pretreatment, the combined VCM production process has a high steam consumption in the various processing steps that are necessary for thermal separation of the diverse intermediate material mixtures. Despite steam credit for the integrated heat recovery in the central vent gas incineration plant and for recovery of reaction heat from the exothermic oxychlorination reaction (generation of steam at 20 bar) and the exothermic chlorination of oxychlorination vent gas (generation of steam at 1.5 bar), the specific steam consumption amounts to 1.74 t per tonne of VCM with 55 % conversion rate at EDC cracking.

The consumption of electrical energy for pumps, for the refrigeration unit, for the air compressor, and for the combustion air and flue gas suction fan of the vent gas incineration plant was 136 kW · h per tonne of VCM.

Large amounts of natural gas are necessary for firing of the EDC cracking furnace, and for the generation of radiant heat as heat flux for the endothermic cracking process, and as auxiliary fuel for the vent gas incineration plant. Thereby, most of the sensible heat of the superheated reaction product leaving the cracking furnace and of the waste heat of the flue gases used for firing the cracking furnace was lost to the environment, resulting in a specific natural gas consumption of 954 kW · h per tonne of VCM.

Despite the close integration of the VCM process with chlorine-producing and chlorine- or HCl-consuming plants, the old VCM production process was not quite satisfactory in economical or ecological terms.

New Process for Integrated VCM Production. The process changeover aimed at the following objects:

1. Increase of yields, i.e., minimization of formation of byproducts by more selective reactions
2. Utilization of all CHC-containing residues produced in the integrated process with chlorine recycling and heat recovery in a totally closed material recycling loop
3. Reduction of wastewater flow with simultaneous minimization of COD, AOX, and salt load
4. Energy savings in the distillation processing of the particular material streams, and in the EDC cracking unit
5. Energy savings in the vent gas incineration unit by import of external CHC-containing vent gases with high calorific value and by improving the thermal efficiency of the vent gas incineration unit.

Figure 45 depicts the overall process flow and mass balance of the new process built at the end of 1991. The new process became “HCl unbalanced” by crack HCl export to silicon chemistry after special purification [125] and simultaneous shutdown of the perchlorination process for economical and ecological reasons. All residues containing chloroorganic compounds are thermally treated under chlorine and heat recovery in the new HCl generation plant (Fig. 46) [126].

Figure 45. VCM production according to the HCl-unbalanced new process

Figure 46. HCl-generating plant

a) Reactor (combustion chamber); b) Steam drum; c) Quenching vessel; d) Washer; e) Heater; f) Flash drum; g) Cooler; h) Cooler (brine at –15 °C)

The process is based on the following chemical reaction:

$$C_xH_yO_zCl + \left(x + \frac{y-1}{4} - \frac{z}{2}\right) O_2 \rightarrow x\,CO_2 + HCl + \left(\frac{y-1}{2}\right) H_2O$$

$$\Delta H^R_{25\,°C} = -12\,560 \text{ to } -14\,650 \text{ J/kg}$$

Because of an H : Cl atomic ratio of >1.3 : 1 in the residues to be incinerated, the reaction is autothermal and needs no auxiliary fuel.

With a 4 – 6 % oxygen excess related to stoichiometry — required for optimum carbon combustion, i.e., to avoid CO formation — the temperture dependent Deacon equilibrium reaction is shifted to the right:

$$4\,HCl + O_2 \rightleftharpoons 2\,Cl_2 + 2H_2O$$

The following reaction products are formed:

1. Flue gas with the following composition is fed to the oxychlorination unit without inert gas separation:

CO_2	56.8 vol %
Cl_2	1.1 vol %
HCl	32.6 vol %
O_2	3.2 vol %
N_2	6.3 vol %

2. 25 % hydrochloric acid for general usage
3. Flash HCl which is sent to the HCl recovery plant in the gaseous state

The chlorine recovery rate as gaseous HCl is ca. 90 %. The steam production is ca. 4.4 t per tonne of residue, which amounts to ca. 85 % heat recovery related to the calorific value of the residues.

The CHC residue mix is converted to gaseous HCl by reaction with oxygen at a pressure of 8 bar gauge and at an extremely high temperature (up to 2500 °C in the flame). The HCl formed is recycled to the oxychlorination unit without expensive compression or inert gas separation steps [126-128]. Use of pure oxygen instead of air has the advantages of an extremely high flame temperature and very long residence times in the combustion chamber. This guarantees (1) quantitative conversion of CHC to CO_2, H_2O, and HCl (in addition to traces of chlorine according to the Deacon equilibrium reaction), and (2) complete destruction of polychlorinated biphenyls (PCB) and polychlorinated dibenzodioxins and dibenzofurans (PCDD, PCDF) being present in trace amounts in the heavy ends and EDC – VCM tars [129] and also preventing their de novo synthesis (destruction rate for PCB: 99.99999 %, for PCDD/PCDF: 99.992 %). By operating this HCl generation plant, the material recycling loop is totally closed. To save auxiliary fuel (natural gas) and satisfy the internal site demand for 20 % hydrochloric acid, part of the liquid light ends and fuel-rich CHC-containing vent gas from other plants are incinerated in addition to the VCM vent gases in the central HCl recovery plant with heat recovery. By installation of a boiler feedwater preheater [130], the thermal efficiency of the vent gas incinerator was strongly enhanced and the water vapor content in the purified flue gas drastically reduced. Even though liquid light ends were incinerated in addition, the PCDD – PCDF content in the purified flue gas is less than 0.1 ng/m^3 (STP) calculated as international toxicity equivalents (ITEQ). Besides, the so-called fugitive emissions were extensively reduced by technical measures such as canned pumps, grooved gaskets, emission-free sampling devices, and sucking off open drains and wastewater collection pits in the direction of the vent gas incinerator. Thus, the total output of toxic compounds into air could be reduced by 90 % in combination with technical measures for increasing the on-stream factor of the HCl recovery plant (e.g., by improving burner control and selecting more resistant construction material). Improvements in the EDC washing unit [131] led to a drastic reduction of the COD load of the wastewater. Process improvements in the oxy stripper led to steam savings and a nearly quantitative hydrolysis of chlorinated ethanol to glycol and glycolaldehydes, followed by essential reduction of wastewater AOX load. The overall stripping efficiency was increased drastically. Surficial wastewater is collected in a 200-m^3 basin and purified in an adsorber (Fig. 47). The new process saves energy (steam consumption only in the desorption step) and is very efficient in terms of AOX reduction and elimination [132]. All these improvements resulted in a higher overall purification efficiency with a reduction of the total wastewater flow of about 25 % (see below):

Old process

Alkaline stripper for COD-containing wastewater

Acidic stripper for inorganic wastewater ($FeCl_3$ containing) with low COD

Neutral stripper for surficial wastewater

Wastewater flow:	235 577 t/a
CHC recovery:	2 538 t/a
CHC composition:	46.7 wt % 1,2-$C_2H_4Cl_2$
	49.2 wt % $CHCl_3$
	2.0 wt % C_2H_5Cl

Remainder: other chlorinated C_1 – C_4 hydrocarbons

Purification efficiency:	99.75 %

New Process

Improved alkaline stripper for COD-containing wastewater

Improved acidic stripper for inorganic wastewater ($FeCl_3$ containing) with low COD

Adsorptive purification of surficial wastewater at pH≈1

Wastewater flow:	178 780 t/a
CHC recovery:	1 156 t/a
CHC composition:	75.2 wt % 1,2-$C_2H_4Cl_2$
	22.0 wt % $CHCl_3$

	1.6 wt % C_2H_5Cl
Remainder: other chlorinated $C_1 – C_4$ hydrocarbons	
Purification efficiency:	99.95 %

Simultaneously, the biological sewage treatment plant was extended by a second stage that additionally treats municipal wastewaters (improving the AOX elimination rate) and by a biosludge (fluidized-bed) incinerator with flue gas purification. The CHC of the return cooling water and steam condensate of the VCM plant is measured by on-line analyzers (semiconductor sensor, FID) to recognize small leakages very quickly. In connection with operating instructions for directives in case of a leak, CHC input into the main outfall ditch because of leakages is drastically decreased. All these measures contribute to keeping the AOX content in the effluent of the biological sewage treatment plant distinctly below the existing regulatory emission levels (max. 20 g AOX per tonne of pure EDC or max. 1 mg AOX/L, or max. 5 g EDC per tonne of pure EDC or 2.5 mg EDC/L, both as monthly averages).

Production-integrated improvements have been achieved by long-term research in the field of chemical catalysis and radical chain pyrolysis. The improvements are more selective catalysts for oxychlorination with increased activity [133] (fewer byproducts, higher HCl conversion, lower degree of ethylene oxidation rate), an improved catalyst for chlorination of the oxychlorination vent gases [134] (nearly quantitative ethylene conversion by increased activity and, because of increased selectivity, much lower formation of chlorinated ethanols that interfere with the VCM process); and a totally changed heat flux system for EDC pyrolysis [135] which, by using the so-called reverse heat flux technique, reduces the amount of byproducts and coke produced even at cracking depths around 60 %. By chlorination of a small portion of recycle EDC a benzene concentration of <500 ppm in the feed EDC could be achieved [136]. This influences the cracking kinetics favorably and less coke and VCM tar were produced. Chloroprene removal from total recycle EDC was distinctively improved [137]. Further ressource saving and byproduct lowering effects were obtained by improving acetylene removal from cracking HCl by selective hydrogenation [138] and by amending the reaction parameters of direct chlorination [139].

With the pinch technology (⟶), important energy savings were obtained. At first, all material streams had to be summed up. Based on this, hot process streams with a technically utilizable temperature level were coupled with heat-absorbing process steps [135], [140]. Also the steam consumption of EDC distillation and EDC vaporization into the cracking furnace could be reduced further [131], [135], [137]. In combination with an open heat pump for reboiling the especially energy-consuming heavy ends column (so-called vapor thermocompression) [141], [142], the specific steam consumption of the VCM process has been lowered to 0.25 t per tonne of VCM including steam production in the oxychlorination unit and in the HCl recovery and HCl generation plant. Further steam could be saved as a side effect of the thermocompression in the VCM column, in the liquid feed EDC preheat before entering the cracking furnace, and in the EDC vaporization into the cracking furnace. The increased electrical power consumption for vapor recompression (ca. 45 kW · h per tonne of VCM) is more than compensated by the overall energy savings. These overall energy savings reduce the consumption of natural gas by a total amount of 24.5×10^6 m^3 (STP)/a, resulting in less emission of CO_2 (51 940 t/a) and $(NO)_x$ (21.9 t/a).

Figure 47. Flow sheet of an adsorber plant (specific steam consumption: 42 kg per cubic meter of wastewater, 70 % less than a steam stripper with feed-bottom heat exchanger)

a) Working adsorber, 2 m^3; b) Standby adsorber, 2 m^3; c) FID analyzer for breakthrough determination

Ecological and Economical Evaluation of the New Process. By the economically and ecologically significant utilization of residues from the integrated VCM production process, an amount of chlorine is saved that corresponds to the flow of recycled HCl. In addition, HCl or salt-containing wastewaters are avoided. Due to the combination of the HCl recovery and generation plant and the AOX pretreatment of wastewater with recycling of CHC removed from wastewater, the new process for manufacturing EDC and VCM is nearly emission and residue free. The HCl generation plant makes the VCM process totally self-sufficient in terms of residue utilization. In combination with measures for process optimization that save ressources and energy, the specific input data and the environmental pollution balance could be demonstrably improved in relation to the old process (Table 2). The potential for the formation of chlorinated dibenzodioxins and -furans has been reduced. Remaining amounts are destroyed almost quantitatively. A shift of dioxin emissions to residues and wastewater is therefore avoided. These successfully operating production-integrated improvements for environmental protection are fundamentally based on the combined material balance with closed-loop material recycling. High investment costs were necessary for the chemical engineering of the new integrated process, including new equipment, and for proper design of the operation and reaction control parameters supported by a modern computerized process control system with video terminals. Extensive research and development work over years required additional capital costs for thorough investigation of each process step.

Table 2. Comparison of specific input and output data in VCM production (Target products are each 225 000 t/a VCM, 30 000 t/a HCl for export, and 25 800 t/a 20 % hydrochloric acid for total site demand)

Substance or energy	Old process	New process	Change, %
Input			
Ethylene, kg per tonne VCM	478	471	–1.5
Chlorine[a], kg per tonne VCM	628.8	592.4	–5.8

Electrical power, kW · h per tonne VCM	136	188	+38.2
Steam, t per tonne VCM	1.74	0.25	–85.6
Natural gas, kW · h per tonne VCM	954	835	–12.5
20 % Hydrochloric acid, kg per tonne VCM	6	3	–50.0
Caustic[b], kg per tonne VCM	40	15	–62.5
Process water[c], m^3 per tonne VCM	0.86	0.56	–34.9
Output			
Coke, g per tonne VCM	90	45	–50.0
Wastewater, m^3 per tonne VCM	1.05	0.77	–26.7
COD, kg per tonne VCM	15	1.3	–91.3
AOX, kg per tonne VCM	0.35	0.14	–60.0
NaCl[b], kg per tonne VCM	50	15	–70.0
Vent gas purified, m^3 (STP) per tonne VCM	1220	979	–19.8
Residue (heavy ends, tar), kg per tonne VCM	28	0	–100.0
CO_2[d], kg per tonne VCM	776.7	588.7	–24.2
$(NO)_x$ as NO_2[d], g per tonne VCM	585.9	437.9	–25.3
∑ Toxic compounds (air), kg per tonne VCM	4.9	0.5	–89.8

[a] Including HCl export – import and production of 20 % hydrochloric acid.
[b] Neutralization of oxychlorination reaction water, wastewater of EDC acidic wash, surficial wastewater, or acidic wastewater from flue gas scrubber of heavy ends – tar incineration.
[c] Demineralized water, however, without boiler feedwater for internal and external steam production.
[d] Integrated vent gas and liquid residue incineration, external residue incineration (old processes), cracking furnace firing, and electrical power and steam production in a thermal power station required for VCM production.

2.2.5. *Examples from Hüls*

2.2.5.1. *Integrated Environmental Protection in Cumene Production* (⟶ Hydrocarbons – Cumene)

Introduction. Hüls has produced cumene since 1954 at its site in Marl. The production capacity is 150 000 t/a. Cumene is used mainly in the production of acetone and phenol, and also in the production of cumene sulfonate, which is a raw material for detergents. It is produced by Friedel – Crafts alkylation of benzene by propene, catalyzed by aluminum chloride, which does not give cumene exclusively, but also produces di- and triisopropylbenzene.

Other side reactions also occur to a small extent. Whereas the polyalkylated isopropylbenzenes can be converted to the target product cumene by using aluminum chloride as the catalyst, other byproducts, which include a high proportion of ethylbenzene, must be removed from the reaction mixture.

Conventional Method of Producing Cumene (Fig. 48). In the past, the Friedel – Crafts alkylation of benzene was carried out together with the conversion of the polyalkylated isopropylbenzenes in a single reactor (a). The catalyst was produced directly in the reaction mixture from aluminum chippings and HCl. It formed a second separate organic phase in the

reactor. The water present in the propene was simply removed mechanically, whereas the benzene used was dried over sodium hydroxide.

After removal from the reactor, the catalyst was decomposed by addition of water, and the liberated aluminum chloride was extracted (b) into the aqueous phase. However, the amount of water required was determined not by the extraction parameters but by the decrease in temperature required for the water washing. Thus, a high excess of cold water was added to the hot reaction mixture to obtain the desired mixing temperature.

Subsequent distillative processing (c) led to the following

1. The target product cumene
2. Polyalkylated isopropylbenzenes, which were returned to the reactor
3. Low-boiling products, which were used as motor gasoline
4. Medium-boiling products, which were processed within the Hüls organization to produce synthesis gas
5. High-boiling products, which were used first as solvents in the production of styrene and then as raw materials for the production of synthesis gas

Figure 48. Cumene production — old process

a) Reactor; b) Extraction; c) Distillation; d) Purification

New Process for Cumene Production [143] (Fig. 49). The new process for the production of cumene was introduced between 1986 and 1988. Its most important features were an increase in the selectivity of cumene formation and suppression of undesired side reactions that do not lead to monoalkylated or polyalkylated isopropylbenzenes. This was achieved by the following modifications to the process:

1. Catalyst production in a separate reactor (a)
2. Avoidance of a second organic catalyst phase in the alkylation reactors (b)
3. Separation of the alkylation of benzene by propene from the reaction of the recycled polyalkylated isopropylbenzene with benzene
4. Complete dehydration of the starting materials benzene and propene by distillation

Figure 49. Cumene production — new process

a) Catalyst production; b) Reactors (several stages); c) Extraction; d) Distillation; e) Purification

An improvement in the distillative processing of the reaction mixture enabled ethylbenzene to be isolated in a pure state and used as starting material in styrene production.

Because of the total dehydration of the starting materials, catalyst consumption and the associated contamination of wastewater by inorganic substances were reduced. The amount of wastewater could be lowered by separating the cooling of the reaction mixture from aqueous extraction of the catalyst. Since the low temperature necessary for extraction could now be adjusted by indirect cooling, the amount of wastewater produced is determined only by the operating parameters for the extraction. The water produced in the extraction can be recycled many times.

Due to the introduction of heat recovery in the distillation process, the energy consumption of the entire process was decreased. Whereas formerly the heat of condensation was removed without utilization, it is now used to produce process steam and hot water, which are fed to the supply networks of Hüls at Marl.

Results. A comparison of the old cumene process (1980) with the new (1990) shows that the amount of wastewater is now 5 % of the former amount, the organics content of the wastewater after passing through the water treatment plant is 1 % of its former value, and the amount of residues has been reduced to 50 % of the earlier figure. Energy consumption, despite additional requirements for distillative processing of the starting materials, has been reduced by 60 %. The gaseous emissions of organic substances, which were already very low, have been prevented completely by passing the waste gases through an existing incinerator.

2.2.5.2. *Production of Acetylene by the Hüls Plasma Arc Process (* ⟶ Acetylene – Production from Liquid Hydrocarbons (Plasma Arc Process)*; ⟶)*

Production and Use of Acetylene. As a result of its strongly unsaturated character, acetylene reacts readily with many compounds. During the early development of industrial organic chemistry, it was one of the most important starting materials for a large number of products. Since the 1940s (United States) and the 1950s (Europe), it has been largely replaced by ethylene and other olefins. Bulk products still produced from acetylene include butanediol and vinyl compounds (vinyl chloride, vinyl ethers, and vinyl esters).

An important feature of acetylene production is the high energy requirement due to the formation of a triple bond. In the Hüls plasma arc process, the energy is supplied by an electric arc. Hydrocarbons are fed to the electric arc reactor in

gaseous form and are pyrolyzed at high temperature (>2000 K). At these temperatures, acetylene is formed in preference to other hydrocarbon compounds. To suppress further reaction to carbon and hydrogen, the hot crack gas must be cooled rapidly (a few microseconds) to low temperatures.

In the electric arc reactor, which has a power consumption of 8 – 10 MW, ca. 1 t/h acetylene is produced from ca. 2 t/h hydrocarbons. The composition of a typical reaction gas mixture is given below.

C_2H_2	16 vol %
H_2	60 vol %
CH_4	10 vol %
C_2H_4	8 vol %
C_3 compounds	2 vol %
C_4 compounds	1.5 vol %
Higher alkynes	1.5 vol %
Residues	1 vol %
Carbon black	0.4 kg per kilogram C_2H_2

The hot reaction gas with this composition is processed in the following main steps:

1. Cooling
2. Removal of carbon black, higher-boiling hydrocarbons (aromatics), and polyunsaturated compounds
3. Purification of acetylene and byproducts such as hydrogen and ethylene

Hüls has produced acetylene since 1939 by electric arc technology. Until acetylene was superseded by ethylene as starting material for poly(vinyl chloride) manufacture in 1992, the production capacity was 12×10^4 t/a using 18 electric arc groups. After this changeover, the supply of the remaining consumers has been satisfied by using a new method of processing the crack gas that was developed jointly with the company Linde. This method meets the stricter present-day ecological and economic requirements. This was achieved mainly by techniques of production-integrated environmental protection.

Old Production Process. The relevant steps of the old process are shown in the flow diagram in Figure 50. Hot crack gas from the electric arc furnace was quenched to ca. 200 °C with water to enable most of the carbon black to be removed in cyclones. The quench water condensed in a further scrubbing step with water at ca. 50 °C, and the remaining carbon black was removed at the same time. After mechanical removal of carbon black the heated wash water was cooled by direct contact with air in a cooling tower and recycled to the cooler. Excess water was fed to the wastewater treatment plant. Both carbon black fractions recovered were used as fuel.

Figure 50. Flow diagram of the old Hüls acetylene process

The high-boiling, mainly aromatic compounds were washed out with special oil fractions and then recovered by distillation.

The crude gas so obtained was compressed; acetylene was absorbed at increased pressure in water and then desorbed as crude acetylene for further purification by decompression. The wash water was fed into the recycling system, some of it being cooled by direct contact with air. The remaining hydrocarbons in the crude gas were recovered by cryogenic processes involving gas liquefaction.

The polyunsaturated and hence energy-rich compounds recovered in the acetylene purification stage were thermally treated, and the polymerizate so obtained could be used as fuel without problems.

The main reasons for the high emissions and high wastewater contamination were the large, partly open water recycling systems. The emissions consisted of hydrocarbons and HCN formed in the electric arc reactor from the reaction of the nitrogen present in the starting materials.

Of the electrical energy supplied, ca. 50 % was utilized for chemical reactions. The rest (thermal energy) was not used.

New Production Process. The flow diagram of the new plant is given in Figure 51. The main difference between the new and the old processes is that the hot reaction gas from the electric arc furnace is quenched with water only to the temperature level at which it is cool enough for no further reaction of acetylene to carbon black and hydrogen to occur on subsequent cooling in a heat exchanger.

Figure 51. Flow diagram of the new Hüls acetylene process

The thermal energy of the hot reaction gases is used to produce hot steam in a heat exchanger of special design and operational features that prevent the formation of deposits by the hot carbon black present in the gas.

The carbon black is recovered mainly in cyclone separators, and the gas is further cooled by washing with oil, which also removes the high-boiling aromatics. Heavy fuel oil is used as the washing medium, and this, together with the remaining carbon black, is used to produce synthesis gas. The “dry carbon black” from the cyclone separators is used as fuel in the power station.

The reaction gas is cooled to ambient temperature in a water spray column, and the quench water that condenses is fed back in a closed cycle to the electric arc reactor. The gas is then compressed and subjected to a sequence of scrubbing operations with selective solvents [i.e., methanol, octane, and *N*-methyl-2-pyrrolidone (NMP) in that order]. The solvents are regenerated by low-pressure stripping with gas fractions from the production process. This removes mainly the polyunsaturated hydrocarbons.

The acetylene-free gas stream from the NMP wash is first passed through a cryogenic separating stage (cold box) which removes most of the remaining hydrocarbons. These are used first as stripping gas in the regeneration stages of the washing processes described above and are then recycled to the electric arc process. The raw hydrogen stream from the cold box is processed in the pressure swing adaptation (PSA) plant to pure hydrogen and waste gas for heating purposes.

The formation of HCN is almost completely prevented by using virtually nitrogen-free hydrocarbon raw materials. Small residual amounts of HCN are effectively removed by scrubbing with NaOH.

Improvements Resulting from the New Process. The new process is characterized by a high degree of heat recovery and the use of closed cycles. This gives the following improvements:

1. Increase in the thermal efficiency from ca. 50 % to the present figure of 75 %
2. Drastic reduction in the amount of wastewater to be treated in the wastewater treatment plant
3. Prevention of emissions of hydrocarbons and HCN
4. Utilization of the residual carbon black and polyunsaturated hydrocarbons that are recovered in the scrubbing processes

Considerable economic benefits have been obtained:

1. Lowering of energy consumption and wastewater costs
2. Lower personnel requirements
3. Improvement in product purity

2.2.6. *Low-Residue Process for Titanium Dioxide Production (Example from Kronos International)*

General. Titanium dioxide pigment is an important industrial intermediate for multiple utilization in various areas (paints and coatings, printing inks, plastics, man-made fibers, paper, etc.) [144]. The raw materials for pigment production contain titanium dioxide associated with oxides of other metals, mainly iron. The only way to isolate titanium dioxide from this oxide mixture in pigment-grade purity is by chemical processing.

The first commercial process, the sulfate process, uses concentrated sulfuric acid as reagent. After use, the acid cannot readily be recycled because of its content of metals and water taken up during the process. Therefore, this acid (so-called spent acid) was typically discarded as waste. Because of the large acid quantities involved, the (conventional) sulfate process became increasingly obsolete and had to be improved to a modern version [145].

An alternative to the sulfate process is the chloride process for titanium dioxide pigment manufacture, using chlorine as reagent [146], [147]. Since regeneration and recycling of chlorine after use have always been an integral part of this process, it never was impaired by a problem such as the disposal of spent acid from the sulfate process. Thus, the chloride process has become more and more successful and has already gained equal or even greater importance than the sulfate process, although it was developed considerably later.

Conventional (Sulfate) Process (⟶ Pigments, Inorganic – Sulfate Method). Raw material is either an ilmenite ($FeTiO_3$) concentrate from beneficiation of naturally occurring ilmenite or a slag obtained from ilmenite by electrosmelting and tapping off the major part of the iron as pig iron for further use. The titaniferous material is digested with concentrated sulfuric acid, leading to a solution of sulfates of most of the metals contained in the ore, e.g.:

$$FeTiO_3 + 2\,H_2SO_4 \rightarrow TiOSO_4 + FeSO_4 + 2\,H_2O$$

The insoluble solids (unreacted ore, gangue) are separated, and part of the iron(II) sulfate is crystallized and recovered (this part of the process generally being omitted when starting from slag). Subsequently, titanium is selectively precipitated by hydrolysis

$$TiOSO_4 + 2\,H_2O \rightarrow TiO(OH)_2 + H_2SO_4$$

Subsequent filtration yields the spent acid filtrate and a cake of aqueous titanium oxide. Thorough washing of the cake, calcination, grinding, surface treatment in suspension, filtration, drying, and micronizing finally lead to the titanium dioxide pigment product. These process steps result in some slightly acidic effluents.

The spent acid obtained by the filtration step after hydrolysis is diluted sulfuric acid, 18 –23 wt % H_2SO_4, containing dissolved sulfates of iron and other metals from the raw material. In the conventional process, ca. 6 – 9 t of spent acid is generated per tonne of pigment, depending on the raw material used. The spent acid was discharged into rivers, coastal waters, or the high seas [148]. Formerly, the recovered iron(II) sulfate (when using ilmenite as raw material) was redissolved in the spent acid and discarded as well.

Modern Sulfate Process. The sulfate process was thoroughly optimized to reduce the quantity of spent acid and increase its H_2SO_4 concentration. Nevertheless, a substantial amount of spent acid remained; its low H_2SO_4 concentration and its metal sulfate content prevented direct recycling to digestion. Further improvement of the conventional sulfate process by alterations proved impossible, and attempts to commercialize a novel sulfate process with direct recycling of all the spent acid failed. Therefore, further processing of the spent acid was mandatory. In some countries, the spent acid is concentrated somewhat and then used for fertilizer production. In other countries, especially those that have few natural gypsum deposits, the spent acid is reacted with calcium compounds to produce gypsum for use (e.g., in plasterboard manufacture).

Another solution to the spent acid problem is improving its quality by concentration and purification to the extent that it can be completely recycled to the digestion step in pigment production. This alternative is adopted, for example, by all producers in Finland, Germany, and Spain. Although individual plants may differ in some details, the multiple-step reprocessing and recycling of spent acid generally consist of [146], [149-151]:

1. Concentrating the spent acid up to 60 –75 wt % H_2SO_4 where the dissolved metal sulfates have a minimum solubility and are mostly crystallized.
2. Separation of the solid metal sulfates (so-called filter salt) from the acid by filtration. Sometimes, the acid filtrate can be recycled directly to digestion; otherwise, further concentration up to 80 – 90 % H_2SO_4 is required before recycling.

The separated metal sulfates can be processed further by thermal decomposition to generate metal oxides (mainly iron oxide) and sulfur-dioxide-containing gas, which is then processed to virgin sulfuric acid as in conventional pyrite roasting – sulfuric acid plants.

When ilmenite is used as raw material for pigment production, the spent acid contains large amounts of dissolved iron(II) sulfate. In this case, spent acid treatment starts with process steps permitting the recovery of a major part of the iron(II) sulfate before further concentration. This iron(II) sulfate or copper as, $FeSO_4 \cdot 7\,H_2O$, is marketed jointly with the copperas recovered during titanium dioxide production. In Germany, for example, none of the copperas produced is discarded any longer; rather, it is utilized, as such or after further processing, for multiple environmental purposes (water treatment, effluent or sludge treatment in sewage plants).

Chloride Process. The chloride process (see Fig. 52) was developed and commercialized as an alternative to the sulfate process. The processing of titaniferous raw materials (ilmenite, slag, or rutile) occurs via the metal chlorides, by using chlorine as reactant and carbon as a reducing reagent, e.g.:

Figure 52. Flow diagram of the chloride process for production of titanium dioxide pigment

$$TiO_2 + FeO + 3\,Cl_2 + 2\,C \rightarrow TiCl_4 + FeCl_2 + CO + CO_2$$

This exothermic reaction takes place at ca. 1000 °C. The reaction products are gases, and after fractional condensation, solids separation, and distillation, sufficiently pure, liquid $TiCl_4$ is produced. The $TiCl_4$ is then reacted with pure oxygen to generate titanium dioxide pigment:

$$TiCl_4 + O_2 \rightarrow TiO_2 + 2\,Cl_2$$

Chlorine is separated from the solid pigment and directly recycled to the first step, chlorination. The pigment may be surface treated in suspension and further processed in the same way as sulfate pigment.

Ecological Aspects of Modern Production Processes. *Sulfate Process.* The conventional sulfate process is characterized by a linear flow of sulfuric acid through the process. Some H_2SO_4 ends up in the copperas byproduct, but the main part remains separate from the pigment end product, as a used reagent with deteriorated quality in terms of concentration and purity. Formerly, this large stream was discarded as waste (see Fig. 53). Now, the spent acid is recovered, and complex acid concentration and filter salt treatment plants are added to recycle the acid entirely. Hence, the modern sulfate process plant for titanium dioxide pigment manufacture is characterized by a closed sulfuric acid cycle that completely withholds spent acid from the environment (see Fig. 54).

Figure 53. Mass flow in the conventional sulfate process

Figure 54. Mass flow in the modern sulfate process

This production-integrated recovery could not be achieved by process redesign; new, separate process units had to be added to the essentially unchanged conventional manufacturing plant. Thus, not only did closing of the acid cycle require substantial investment, but energy requirements increased considerably as well. A substantial amount of fossil fuel is required as such — for thermal decomposition of the filter salt — or indirectly in the form of valuable steam for water evaporation in acid concentration. Parts of these additional energy requirements cannot be recovered but are lost to the environment via cooling towers and off-gases.

Chloride Process. In contrast to the sulfate process, the chloride process has the great benefit that the reagent chlorine is recycled directly without major treatment, this recycling being an integral part and an inherent characteristic of the process right from the beginning. In past years, the chloride process has increasingly been used in construction of new titanium dioxide pigment factories or even for replacing obsolete sulfate process-based plants to cope with the spent acid problem.

Process Engineering Equipment Aspects. Spent acid treatment and concentration as part of the modern sulfate process were possible only because of the availability of improved construction materials and equipment items permitting the safe handling of this highly corrosive substance.

Chloride process technology, plant design, and equipment are entirely different from sulfate process technology. Its commercialization required considerable development and engineering efforts. Safe operation is possible because of high-technology equipment and sophisticated control technology.

2.2.7. *Reduction of Waste Production and Energy Consumption in the Production of Fatty Acid Methyl Esters (Example from Henkel)*

Fats and Oils: The Raw Materials of Oleochemistry. Fats and oils are triglycerides (i.e., fatty acid esters of glycerol). They are the starting materials for the production of fatty acid methyl esters, which are important intermediates in the production of fatty alcohols and surfactants [152] by the oleochemical route, which has great ecological benefits [153]. The fatty acid methyl esters are produced either by the esterification of fatty acids after hydrolysis of the triglycerides or by direct transesterification with methanol. The overall transesterification reaction is as follows:

This is actually the result of three consecutive reactions because the fatty acid groups of the triglyceride are rearranged sequentially. Transesterification can be carried out at a relatively low temperature (60 °C) in the presence of an alkaline catalyst (e.g., an alkali-metal alcoxide or hydroxide).

The fat or oil raw material is not a pure triglyceride since significant amounts of other components are also present. Quantitatively, the most significant of these are free (unesterified) fatty acids (1 – 5 %), which neutralize the transesterification catalyst so that the consumption of catalyst can sometimes be very high. The catalyst dissolves in the coupled product glycerol and must be removed as a salt at the end of the process.

Minimization of catalyst consumption is desirable for environmental reasons; therefore, the free fatty acids contained in the oil must be neutralized.

Low-Pressure Transesterification — Old Batch Process. In the old batch transesterification process, neutralized oil is used. The oil is treated with aqueous sodium hydroxide to neutralize the free fatty acids (see Fig. 55). The aqueous phase, which contains a high proportion of the soaps formed (soap stock), is then removed by means of separators, and the remaining soap residues are removed from the oil by washing with water several times (usually twice). These soap residues are then separated [154], [155]; the wash water and the aqueous phase from the first stage, which has a high soap content, are bulked together and treated with sulfuric acid. The soaps are thereby split to form fatty acids and sodium sulfate. The fatty acids can be separated as an organic phase by decantation. The water, which contains sodium sulfate and organic impurities, must be treated in a wastewater treatment plant. The fatty acids produced are a low-value coupled product.

Figure 55. Flow diagram of alkaline refining

The oil, which is free of fatty acids, is then dried and transesterified (Fig. 56). The batch transesterification process represents the usual state of technology [156]. The process is operated in as simple a way as possible.

Figure 56. Low-pressure transesterification — batch process

Sodium hydroxide dissolved in methanol is used as the catalyst for methanolysis. A high proportion of the sodium hydroxide is converted to sodium methoxide in the solution [157], liberating water:

$$NaOH + CH_3-OH \rightleftharpoons NaOCH_3 + H_2O$$

The dried oil is mixed with methanol and the catalyst solution, and the reaction mixture is pumped into a stirred tank. The reaction is completed there at 80 °C as a batch operation. The methanol that evaporates is completely condensed and returned to the reactor.

At the end of the reaction, excess methanol is partly distilled off. The mixture of fatty acid methyl ester and glycerol is pumped into a settling tank to allow phase separation. After standing for several hours, the lower phase (glycerol phase) is separated. The upper ester phase is removed and temporarily stored before further processing (e.g., hydrogenation to fatty alcohols).

Although excess methanol has been distilled out of the reactor, the glycerol phase still contains methanol, which must be removed before further glycerol processing. Removal of residual methanol is carried out continuously. The glycerol is cooled again and treated with acid in a stirred vessel in a batch process. The sodium soaps formed from the catalyst (see reaction equation), which are almost completely extracted from the mixture by the glycerol,

$$NaOH + CH_3\text{-}O\text{-}\overset{\overset{\displaystyle O}{\|}}{C}\text{-}R \rightarrow NaO\text{-}\overset{\overset{\displaystyle O}{\|}}{C}\text{-}R + CH_3OH$$

are decomposed, forming fatty acid and sodium salt:

$$NaO\text{-}\overset{\overset{\displaystyle O}{\|}}{C}\text{-}R + \text{acid} \rightarrow H\text{-}O\text{-}\overset{\overset{\displaystyle O}{\|}}{C}\text{-}R + \text{salt}$$

The fatty acids can be separated after a short time as the upper phase.

The old batch transesterification process has the following disadvantages:

1. Transesterification is carried out in only one step, so that a large excess of methanol is necessary to give a high conversion efficiency.
2. The catalyst used is sodium hydroxide dissolved in methanol. Water is formed in the course of alcoxide formation.

In the presence of water, the sodium hydroxide present reacts very quickly with fatty acid methyl esters to form sodium soaps. Under these conditions, the soaps formed are not effective catalysts.

For this reason, large quantities of catalyst must be used. This leads to product loss and to large quantities of fatty acids in the crude glycerol after soap splitting. Furthermore, the crude glycerol then has a high salt content. This amount of salt must be removed in subsequent processing and disposed of as waste.

New Method of Low-Pressure Transesterification. The modified process has the following aims:

1. Continuous operation
2. Utilization of the free fatty acids contained in the oil
3. Prevention or minimization of waste products and residues
4. Optimum utilization of the raw materials used, especially reduction in the amount of catalyst and the amount of excess methanol required
5. Heat recovery and optimization of energy consumption

Neutralization of Oils by Pre-Esterification. The free fatty acids present in the raw material are esterified with methanol. The proton-catalyzed esterification can be carried out homogeneously [158]. However, the result is that some of the acidic catalyst is also esterified, and the ester and catalyst must then be separated by a water wash. This results in wastewater that sometimes contains toxic substances [159].

To avoid this problem, a heterogeneous catalyst [157], [160-162] is used (see Fig. 57) consisting of a strongly acid macroporous ionexchange resin arranged in a fixed-bed reactor. The reaction temperature is between 60 and 80 °C.

Figure 57. Flow diagram of pre-esterification

In pre-esterification, not only are the fatty acids in the crude oil esterified, but so are the fatty acids produced on splitting the soaps formed in the transesterification process (see Fig. 58). Recycling leads to an increased yield of methyl ester. After pre-esterification, excess methanol is separated and removed together with the reaction water.

Figure 58. Low-pressure transesterification — continuous process

The neutralized oil (mixture of triglycerides and methyl esters) is transesterified after addition of methanol and catalyst. Transesterification leads to the formation of glycerol and fatty acid methyl esters. A marked solubility gap exists in the three-component system glycerol – methyl ester – methanol, so that a glycerol phase and an ester phase are formed [162]. This two-phase system gives the possibility of a multistage process. By removing the product glycerol (GLY, see Eq. 1), a high yield of methyl ester (ME) with a reduced consumption of methanol (MeOH) [163] is achieved

$$K = \frac{[\mathrm{ME}]^3 \times [\mathrm{GLY}]}{[\mathrm{MeOH}]^3 \times [\mathrm{TRI}]} \tag{1}$$

Transesterification is carried out in two stages, the glycerol phase formed being removed after each stage.

The reaction is carried out in tubular reactors with a flow rate that ensures good mixing of the two-phase reaction mixture at the beginning and end of the reaction [164]. Since the amount of back mixing is low in these tubular reactors, short reaction times with low catalyst concentrations can be achieved at ca. 80 – 90 °C.

With a new catalyst (alkali-metal oxide), smaller catalyst concentrations can be used than is the case with sodium hydroxide. With suitable reactor design and choice of catalyst, the salt content of the glycerol produced is decreased by 50 %, and smaller quantities of fatty acids are formed in the splitting reaction.

Immediately after transesterification, excess methanol contained in both liquid phases is removed with the aid of a multistage falling-film evaporator. The multistage system enables heat from the hot methyl ester and glycerol to be utilized in the initial evaporation stages.

The recovered methanol at atmospheric pressure is fed to the methanol distillation stage as a vapor.

The soaps in the glycerol from which the methanol has been removed are continuously split with acid. Consumption of acid is minimized by pH control. Concentrated acid is used to minimize the dilution of glycerol with water.

The ester phase, from which the methanol has been removed, still contains undissolved, highly dispersed residual glycerol, which is removed after cooling with the aid of coalescence separators [165]. The use of such equipment avoids the need to wash the esters with water [152]. A highly concentrated crude glycerol is thus obtained, which leads to reduced energy consumption in glycerol processing.

Ecological Aspects of the New Low-Pressure Transesterification Process with Pre-Esterification. In the earlier process, refined oil was used. The waste streams produced in the oil refining process are completely avoided by use of preesterification. Moreover, the waste fatty acid produced in the low-pressure transesterification process can be reutilized.

The reaction is catalyzed by a macroporous cation exchanger. This catalyst has a very long service life and can be disposed of without problems.

By carrying out the transesterification reaction in several stages, the process can be carried out with a lesser excess of methanol. This leads to an energy saving in the methanol recovery and methanol purification processes. The use of a continuous process enables heat to be recovered during the recovery of methanol from the ester and glycerol.

Impure methanol is fed into the methanol purification stage as a vapor, so that the energy consumption in methanol distillation is very low.

The use of an alkali-metal alcoxide in combination with the new reactor design has the advantage of lower catalyst consumption. Since the catalyst is separated along with the byproduct glycerol, this means that the amounts of salt produced in a subsequent glycerol processing stage are greatly reduced.

During the process, crude glycerol is diluted as little as possible (use of coalescence separators) to give reduced energy consumption in glycerol processing and to minimize the amount of wastewater produced.

2.2.8. *Integrated Environmental Protection in the Production of Vitamins (Example from F. Hoffmann-La Roche)*

Introduction. “Etinol” (chemical formula see below) is an important intermediate in the production of vitamins and food dyes, and is produced in a major plant. By using the conventional synthesis route, the raw material consumption of the presented intermediate step is very high, and the byproducts formed pollute environmental compartments such as water and air. To produce 1 kg etinol in a multipurpose apparatus, ca. 3 kg raw material is required, so that ca. two-thirds of the raw materials are lost as waste, some in chemically changed form. This situation is unsatisfactory both ecologically and economically.

In principle, two possibilities exist for reducing the amount of waste: to recover the useful raw materials from waste streams and recycle these to the process, or preferably to modify the process so that raw materials are more efficiently utilized.

Original Process for the Production of “Etinol” in a Multipurpose Plant. The reaction consists of the addition of acetylene to a vinyl ketone using lithium as the process auxiliary according to a very simple-looking overall equation:

However, the reaction must be performed in three complex stages (see below):

In stage I, metallic lithium is dissolved in liquid ammonia at its boiling point (ca. –33 °C). Acetylene is then fed to this solution, first forming dilithium acetylide (“lithium carbide”). Lithium carbide then reacts further with acetylene to form monolithium acetylide and ethylene. In stage II, the vinyl ketone, diluted with an organic solvent, is added to the lithium acetylide, whereupon “lithium etinolate” is formed. The ammonia that served as a solvent in stages I and II of the reaction is then distilled off from the reaction mixture. In stage III the desired product is obtained from the lithium etinolate by hydrolysis with dilute sulfuric acid.

The former industrial method of carrying out this process is shown schematically in Figure 59. Acetylide formation and reaction of the acetylide with the ketone occurred in that order in the same reaction vessel. Ammonia was then removed in a distillation vessel specially designed for that purpose. The resins produced in stage II of the reaction were removed from the product by a wastewater stripper in the production plant. These resins, along with the wastewater that also contained valuable lithium, were sent to the wastewater treatment plant.

Figure 59. Etinol production — flow diagram of original process

As already mentioned, this process had disadvantages, and great efforts were made to improve it. The production of etinol was described as early as 1948 as the most expensive and difficult part of this vitamin synthesis, and the situation had hardly changed by the early 1980s.

Attempts were made at first to replace the lithium needed in the condensation by cheaper metals such as sodium, potassium, magnesium, or calcium. However, all of these attempts failed because either the yields obtained with the alternative methods were poor or other disadvantages had to be tolerated, such as the very long times required to dissolve the metals. Attempted improvements to the method, such as recovering the expensive lithium from the wastewater in the form of a salt, were also unsuccessful because of the high resin content of the wastewater.

New Process for the Production of “Etinol” (Fig. 60). *Improvements Developed in the Laboratory.* Laboratory investigations showed that the vinyl ketone used is unstable in liquid ammonia. Therefore, under the conditions of ethynylation in the absence of lithium acetylide or when it was present in only substoichiometric amounts, resins were produced almost exclusively from the vinyl ketone even though the solution was diluted with an organic solvent. Therefore, experiments were made in which the addition was carried out in an organic solvent instead of ammonia. The laboratory results were overwhelming, the yields obtained were 95 % instead of 80 %, and the lithium excess could be reduced from 20 to 5 %. Production of the undesired resins almost ceased [166].

Figure 60. Etinol production — flow diagram of new process

After these laboratory investigations, pilot plant trials were carried out on a modified process. After formation of the monolithium acetylide in stage I, ammonia is distilled off and replaced by solvent I. The distillative removal of ammonia must be carried out at a controlled heating rate so that the monolithium acetylide –ammonia complex, which is not very stable, does not decompose. The distillation is interrupted at exactly 5 °C. In order to facilitate drying of the solvent, a further solvent change is carried out after condensation, since solvent II can easily be dried and is also used in the following step of the process [167].

As a result of the much reduced amounts of resin, a lithium recovery method could be developed. It became apparent that an aqueous solution of lithium hydroxide was especially suitable for this recycling method, provided organic impurities were excluded. The “lithium etinolate” solution is hydrolyzed in stage III with water instead of sulfuric acid. The mixture so produced is in two phases, which are separated in a decantation apparatus. The aqueous solution of lithium hydroxide, which still contains part of the product in solution, is concentrated in a column. The water – product mixture obtained as overhead product is recycled to the hydrolysis stage, and the 10 % solution of lithium hydroxide that collects at the bottom of the column is returned to the lithium manufacturer for reprocessing. Only the organic phase is subsequently neutralized with dilute sulfuric acid, and high-boiling components are removed in a stripper column. The consumption of sulfuric acid is considerably lower than in the original process since lithium is obtained not as a salt but as the hydroxide. The amount of sulfuric acid is only that required to neutralize ammonia liberated from the monolithium acetylide – ammonia complex.

Process Changes: Optimization. In the original process, considerable quantities of acetylene and ammonia had to be disposed of as waste products. After the drastic reduction in the amount of resin produced, the consumption of these raw materials could be carefully scrutinized. Improvements can be achieved by:

1. Lowering of acetylene consumption by a modified reaction design
2. Recirculation of acetylene and ammonia by means of an absorption – desorption system
3. Utilization of the calorific value of the unused acetylene and of the ethylene produced in the process

The acetylene balance (percentage of total consumption) in the original process is approximately as follows:

Consumption in the reaction	30 %
Waste gas as ethylene:	20 %
Waste gas as acetylene:	50 %

The important 50 % loss in the form of acetylene can be recovered and returned to the reaction cycle. All of the waste gases from the steps up to the condensation stage are fed to the central waste-gas recovery system. The gases are first passed through the acetylene absorption plant where most of the acetylene is removed from the waste-gas stream by supercooled ammonia with a low acetylene content. Because the other components of the waste gas are less soluble than acetylene in liquid ammonia they pass through the absorption column. The acetylene-rich ammonia from the bottom of the column goes to a central ammonia – acetylene buffer tank. The gases leaving the acetylene absorption column, together with waste gases from the neutralization stage and from all processes of stage III, are passed through the ammonia absorption column, where the waste-gas stream saturated with ammonia is scrubbed with water. The aqueous ammonia solution in the lower part of the column is retained in the absorption recirculation system long enough for the concentration of ammonia to reach ca. 15 %. The ammonia –water mixture is separated by a pressurized rectification column [168]. The remaining waste gases after ammonia absorption — mainly ethylene and nitrogen with small amounts of acetylene — are fed to the boiler plant for burning as fuel.

Acetylene recovered by the absorption process is reused for lithium acetylide production in stage I of the process. For this, the acetylene-containing ammonia from the central ammonia –acetylene buffer tank is fed into a desorption column where the acetylene is driven off from the ammonia by heating and is obtained as overhead product. Ammonia from the bottom of the column is reused for dissolving metallic lithium or absorbing acetylene.

The idea of burning the high-energy waste gases acetylene and ethylene in an environmentally friendly process to produce steam is certainly attractive. However, serious safety problems must be solved before such a process can be considered. Particular attention must be paid to the safety aspects of acetylene, which is explosive over a wide range of concentrations in air (lower flammability limit 2.3 vol %, upper flammability limit 82 vol %, ⟶ Acetylene – General Safety Factors and Safety Measures) and which can decompose at moderately elevated pressure even in the absence of oxygen, generating large amounts of heat and high pressure. Investigations have shown that self-decomposition can be suppressed by diluting the acetylene with natural gas, even when the gas mixture is ignited. Since the boiler plant runs on natural gas, this principle has been used in combustion of the waste gas. Waste gases from the production plant are diluted to 40 % by injection of a stream of natural gas after they have passed through the absorber; they are then compressed to the pressure required by the boiler plant. Moreover, the production plant itself is separated from the combustion plant by a system of flame arrestors [169], [170].

Energy Considerations. Both the process of dissolving metallic lithium and the condensation of lithium acetylide with ketone are exothermic. Since these reactions are carried out at the boiling point of ammonia (–33 °C), or in any case below 0 °C, a cooling system for very low temperatures is inevitable. The cooling medium used is identical to the reaction solvent (in this case, ammonia). Thus, not only can cooling be carried out without using chlorofluorohydrocarbons, but also any accidental mixing of the cooling ammonia with the ammonia of the process will not lead to problems, since it is identical with the solvent used. The pressure difference guarantees that in case of a leak the only possible flow will be of coolant into the reaction solution. Also, the strong smell of ammonia facilitates leak detection, so that amounts of coolant lost by leakage are very small.

The refrigeration process uses compressors and an expander system. The proximity of the refrigeration machinery enables the compressed hot ammonia to be used as a source of heat in the etinol plant. Thus, the acetylene desorption column used to drive off dissolved acetylene is heated by waste heat from the refrigeration machines. Only the excess heat is removed by a cooling tower, and this requires a minimum amount of cooling water.

Ethylene and acetylene are diluted with natural gas in the gas injection equipment and fed to the boiler plant to utilize the energy they contain. The resins can also be used for energy production with the aid of suitable incineration plants. Thus, the high calorific values of these byproducts and wastes can be used to produce energy in the form of steam and electricity, thereby avoiding the environmental pollution that would result from the burning of fossil fuels.

Environmental Protection Balance. The material flow diagrams for the old process and for the new improved process are shown in Figure 61.

Figure 61. Comparison of mass flow of old and new processes

The presence of lithium salt in the wastewater is avoided. Also, the waste-air streams conform with legal requirements and are all used either in the process or for energy production. Increased recycling of ammonia and acetylene leads to reduction in the consumption of ammonia to 25 % of its former value; acetylene consumption is reduced by 50 %. Thus, the stoichiometric excess of acetylene used in stage I of the reaction is reduced to ca. 12 %.

The increased extent of closed material cycles is remarkable. Not only ammonia and acetylene, but also lithium in the form of lithium hydroxide solution, are recycled. The efforts toward a better environmental compatibility have resulted in a new process that is more complex than the original “straight-through” process. The effects are beneficial for both the ecology and the economy. The performance of new installations is optimized by ensuring that individual process steps harmonize with each other. This applies not only within the identical batch plants used for the different stages, but also to energy utilization in the boiler plant. Operators of these plants are required to have an increased level of understanding. Improved training and education can ensure that consumption of materials is minimized and utilization of equipment and raw materials is maximized.

2.2.9. *Production of Pure Naphthalene without Residues — Replacement of Chemical Purification by Optimized Multiple Crystallization (Example from VFT)*

Formation and Uses of Naphthalene. In the production of coke for use in blast furnaces, coal tar is produced as a liquid byproduct. Raw materials for the chemical industry, metallurgy, and energy production are obtained from this complex mixture of chemical compounds with aromatic character (⟶ Tar and Pitch) [171].

The most important constituent of coal tar with respect to quantity is naphthalene, which is present at a concentration of 10 %. Pure naphthalene (up to 99.9 %), obtained by a refining process, is of great economic importance as a basic chemical for the production of, e.g., phthalic anhydride-based plasticizers, dyes, plant-protection agents, and special solvents (⟶ Naphthalene and Hydronaphthalenes – Physical and Chemical Properties, ⟶ Naphthalene and Hydronaphthalenes – Production, ⟶ Naphthalene and Hydronaphthalenes – Uses) [172].

Chemical Refining. The conventional method of purifying naphthalene uses several stages of physical and chemical treatment:

1. Coal tar distillation
2. Crystallization of the naphthalene fraction
3. Treatment of the crystallized product with concentrated sulfuric acid and formaldehyde, followed by neutralization with sodium hydroxide solution
4. Redistillation to remove dark-colored secondary constituents (Fig. 62)

Figure 62. Flow diagram of old process of chemical naphthalene refining by treatment with sulfuric acid and sodium hydroxide solution

This refining process also produces highviscosity naphthalene-containing acidic resins amounting to ca. 8 % of crude naphthalene. These must be disposed of by dumping.

Also, based on the original weight of coal tar, naphthalene-containing waste sulfuric acid (7 %) and naphthalene-containing dilute sodium hydroxide solution (ca. 18 %) are produced. These waste streams can be neutralized by mixing them together and are then sent to a sewage plant. However, because the material has large amounts of naphthalene-containing oils, sludge deposits are formed that require very complex treatment.

Physical Refining Process (Solution of the Environmental Problem). VFT realized the advantage of preventing the production of waste materials by removing the impurities in naphthalene simply by repeated application of a physical separation process. High selectivity is required to enable the residual oil to be used as a raw material in later process stages without further treatment (Fig. 63).

Figure 63. Flow diagram of new process of physical refining by countercurrent crystallization

To achieve this desirable situation, a new process had to be developed. The phase diagram of naphthalene and the main impurity benzo[*b*]thiophene is given in Figure 64. It shows that with a starting mixture of 90 % naphthalene, a single-stage crystallization gives only a 6 % increase in concentration with a very low yield. On the other hand, a multistage crystallization process can give naphthalene in good yields and high purities that meet market requirements (Fig. 65).

Figure 64. Phase diagram of benzo[*b*]thiophene – naphthalene

Figure 65. Schematic of five-stage crystallization

Process Details and Plant Technology. As an illustrative example, a detailed description of stage 2 of the process is given. The crude naphthalene, together with the residual oil from stage 3 and the crystalline product (C 1) from stage 1, is cooled in the crystallizer at controlled temperature. This causes a layer of crystals with an increased naphthalene concentration (in accordance with the phase equilibrium) to form on the cooled surface of the inner wall of the crystallizer.

The depleted residual melt is recycled to stage 1, and is there separated into a residual oil and the crystallized product (C 1). Benzo-[*b*]thiophene and other impurities in the crude naphthalene remain in the residual oil, which can be processed in adjoining production plants.

Naphthalene shows a marked tendency to undergo heterogeneous seed formation on cooling of the melt [173]. A crystallizer was therefore developed in which the molten naphthalene fraction runs down the interior of vertical tubes as a falling film [174]. During the crystallization phase, the depleted naphthalene oil that runs off the inside of the tube is collected in a vessel and recycled by a pump to the falling-film distributor at the top of the crystallizer. The outside surfaces of the crystallization tubes are covered with a falling film of water, which acts as a cooling or heating medium. The temperature of the water is lowered (crystallization phase) or raised (melting phase) in accordance with a predetermined function.

At the end of the crystallization phase, the liquid residual oil is pumped off. In the next stage of the process, the falling film of water is heated under temperature-controlled conditions so as to give partial melting of the crystal layer on the inside of the tube. This causes melting of that fraction of material that contains a higher proportion of impurities (in accordance with the phase diagram). These fractions are collected separately in the vessel under the crystallization tubes and are distributed to various crystallization stages according to their purity, as shown in Figure 65.

A crystallizer containing >1000 tubes, all 12 m in length, was designed and built to give an economically viable production capacity. Careful attention was given to the design of the crystallizer, the equipment for providing heat energy at the correct rate, and precise process control.

This multistage crystallization process is controlled by a central control system. In this way, the energy and mass flow rates can be continuously balanced in the various crystallization stages. Determination of the process parameters and control of the production program are based on the analytically determined starting concentrations at each stage and the desired separation factors.

Since crystallization is a purely physical separation process, neither solid waste nor wastewater is produced. The comparatively small flows of waste air due only to changes in the contents of the plant are taken to the central waste-gas combustion plant. All impurities in the crude naphthalene are concentrated in the residual oil from stage 1 and can be economically utilized in further processing stages. This naphthalene purification process was installed in the Castrop-Rauxel works of VFT, and has produced >60 000 t/a of pure naphthalene consistently and without problems for more than 10 years.

Benefits of the Plant. The shortage of dumping space has led to a drastic increase in dumping costs, so that production of pure naphthalene by chemical refining is no longer economically possible. Development of this residue-free environmentally friendly process has made a decisive contribution to the stabilization of coal tar utilization in Germany.

2.2.10. *Improvements in the Polypropylene Production Process (Example from Shell)*

Introduction (⟶ Polyolefins – Raw Materials, ⟶ Polyolefins – Industrial Processes). The discovery by ZIEGLER and NATTA of the catalyst system named after them in the 1950s opened the way to the large scale production of polypropylene. Shell companies were among the first to realize the potential of this process and started a development program that culminated in the start-up of Shell's first two polypropylene units in Carrington, United Kingdom (1962) and Pernis, The Netherlands (1963). These plants were very small (capacity 5×10^3 t/a) compared to present-day standards and used first-generation Ziegler – Natta catalysts. These catalysts had a low activity and a low selectivity, making it necessary to remove the catalyst residues as well as the atactic polymer by de-ashing. This process made use of a hydrocarbon diluent, which resulted in relatively low system pressures.

In 1964, Shell Research discovered a catalyst with improved selectivity, which led to a significant rationalization of the production process [175]. The removal of atactic polymer could be omitted because polymer of the desired isotacticity could be made directly in the reactor. The above developments formed the basis for a continuous improvement in plant design, with production capacities steadily rising to 100×10^3 t/a in the late 1970s.

Major Developments since 1980. During the 1980s, two fundamental changes in the polypropylene process led to a

breakthrough in terms of improved process economics, energy efficiency, and reduced environmental impact. The first of these changes was the conversion from a diluent process to a process in which liquid propene acts as both reactant and “diluent” for the reactor slurry. This mode of operation, which is called LIPP (Liquid Propylene Process) leads to a considerable increase in the pressure at which such a process is operated.

The second breakthrough was the use of a high-activity catalyst. This proprietary catalyst called “Shell High Activity Catalyst” (SHAC) was developed by Shell Research and achieved a hundredfold improvement in product yield with respect to the quantity of titanium catalyst employed, leading to a titanium residue in the polymer on the order of 1 to 2 µg/g [176]. As a result, removal of the catalyst residues could be omitted, leading to further process simplification. An impression of the simplification in terms of unit operations between the “diluent” process and new “LIPP” process can be gained from Figures 66 and 67.

Figure 66. Flow diagram of the diluent – slurry process

Figure 67. Flow diagram of the bulk polypropylene process (LIPP)

Capital Cost. Clearly, from the above, the investment cost per tonne of capacity for the LIPP – SHAC process will be appreciably lower because fewer equipment items are required in the streamlined process.

Energy Consumption. Without the need for de-ashing and diluent distillation, and with a more efficient operation due to the higher pressure level in the reactor, major reductions (ca. 50 % expressed in terms of fuel equivalent per tonne of polymer) in the energy consumption of the modern polypropylene plant have been achieved. Figure 68 shows the energy consumption per tonne of polypropylene on changing from a diluent to a LIPP process.

Figure 68. Energy consumption of polypropylene (PP) plants

* Conversion to LIPP process, 1987.

Environmental Impact. With regard to environmental impact, four areas can be identified in which clear progress is evident:

1. *Metal salts* The metal salts that originated from the de-ashing step required disposal. Since de-ashing is no longer needed, their quantity has been diminished by a factor of >100. The only source of metal salts remaining is equipment flushing where small amounts are found.
2. *Diluent* Although extensive precautions are taken to avoid loss of diluent from the plant, this can never be totally prevented. Apart from the fugitive losses of diluent, a loss occurs in the heavy ends fraction of the diluent recovery operation. Since the LIPP process does not use a diluent except for some flushing, the amount of diluent lost is drastically reduced.
3. *Alcohol* In the diluent process, an alcohol is used to deactivate the catalysts. Although the alcohol is recovered from the aqueous stream, a small residual amount will be contained in the wastewater. Since no alcohol is required in the new process, this discharge no longer exists.
4. *Propene* The overall streamlining of the process has resulted in a considerable reduction in fugitive emission of propene from the plant.

The relative improvements in the above-mentioned fields are summarized in Figure 69.

Figure 69. Environmental discharges from polypropylene production processes

Developments Developments are mainly in the field of catalyst improvement, both of conventional Ziegler – Natta catalysts and of single-site catalyst. These developments will mainly influence the properties of the polymer product rather than the manufacturing process.

2.2.11. ***The Zero-Residue Refinery Using the Shell Gasification Process (Shell – Lurgi Example) (see also, ⟶ Oil Refining)***

Introduction. Refineries worldwide are being subjected to increasing pressures, both legislatively and economically. The effects of the Clean Air Act (CAA) in the United States of America are well documented [177]. In Europe, increasing environmental legislation is making itself felt both in refinery operation and in terms of product quality. The former is governed by the requirements of the EC Large Combustion Plant Directive or more stringent national regulations. The latter is dictated by EC Directive EN 228 requiring a reduction of sulfur in diesel motor fuels to 0.05 % S by 1996 and in heating oils to 0.1 % S by 1999.

Simultaneously, a medium-term pressure is occurring to reduce the low-sulfur crude intake of refineries because of declining availability and an increasing cost differential compared with high-sulfur crudes.

Various schemes including either coking or residue gasification have been proposed to cope with these pressures. Realization that coke disposal is becoming increasingly difficult has led to wider application of residue gasification (⟶ Gas Production – Partial Oxidation of Hydrocarbons, ⟶ Gas Production – Hydrogenating Gasification). Four existing refineries in Germany already employ the Shell Gasification Process (SGP) for residue utilization. Worldwide, five plants are currently (mid-1990s) under construction, including a major revamp at Shell's own Pernis refinery near Rotterdam.

SGP in the Refinery Flow Sheet. Before describing the gasification and gas treating technology, the way they fit into the overall picture of the refinery flow sheet should be reviewed. Figure 70 provides a simplified refinery flow sheet after implementation of a combined hydrocracker (HCU) and SGP project. These two units, together with the gas-treating section downstream of the SGP, are shaded in the diagram.

Figure 70. Shell gasification process in the refinery environment

ADU = Atmospheric distillation unit; LOU = Lube oil unit; HDT = Hydrotreating; VDU = Vacuum distillation unit; HCU = Hydrocracker unit; VBU = Visbreaker unit; FCC = Fluid catalytic cracking; HDS = Hydrodesulfurization; SGP = Shell gasification process; Mogas = motor gasoline; LPG = Liquefied petroleum gas

The main environmental contaminants, sulfur and heavy metals, tend to remain in the bottom product of distillation processes. Their path through the refinery is from the crude oil intake via the atmospheric distillation unit (ADU), through the vacuum distillation (VDU) to the visbreaker unit (VBU), a mild thermal cracking process with subsequent distillation facility. In the original flow scheme, prior to implementing the new units all the residue from the visbreaker together with its load of contaminants, typically 2 – 4 % sulfur and up to 400 µg/g vanadium, was sold into the heavy fuel oil pool. This material is largely used in oil-fired power stations, where the restrictions of the Large Combustion Plant Directive are now placing restraints on its use, particularly to reduce atmospheric sulfur emissions.

Reductions in the allowable sulfur content of diesel and heating oil both require the use of more hydrogen in the hydrodesulfurization (HDS) and hydrotreating (HDT) units in the gas oil fractions. The new hydrocracker, whose main purpose is to convert middle distillates into lighter fractions, is also a large consumer of hydrogen.

Reduction in allowable benzene levels in motor gasoline (Mogas), which the CAA requires and which may yet become a requirement in Western Europe, requires a reduction of operating severity on the reformer, which reduces the amount of byproduct hydrogen available from this unit. Environmental pressures as expressed in legislation to reduce sulfur emissions to the environment from refinery products, especially when combined with a reduction of potentially carcinogenic material from gasoline, have the following results:

1. A surplus of high-sulfur fuel oil
2. A large increase in the internal hydrogen demand of the refinery
3. A substantial decrease in the amount of internally generated hydrogen from the reformer

The overall technological concept provides for utilizing the surplus high-sulfur fuel oil to manufacture the hydrogen required to cover the ever-increasing internal hydrogen deficit. It in cludes the construction of a new hydrocracker and the residue gasification unit for the production of hydrogen and sulfur-free fuel gas, which will be fed to a gas turbine that forms the heart of a combined-cycle cogeneration plant. Additionally, it includes new amine treating and Claus units.

The feedstock for the SGP unit is a heavy, vacuum-flashed cracked residue from an existing visbreaker unit. This material is typically characterized by high viscosity and high metal content.

The product hydrogen would be aimed primarily at supplying the hydrocracker. Sufficient flexibility can, however, be built into the gas treatment facilities to accommodate alternative scenarios in the overall hydrogen refinery balance and to produce methanol for methyl-*tert*-butyl ether (MTBE) production or other uses.

Process Description. *General.* When looking at the market possibilities, the sales volume of the product should be matched with the total volume of residue available. Of those products of immediate use in the refinery that can be produced from residues, hydrogen is an obvious choice (⟶ Gas Production – Hydrogen Production Based on Heavy Residues). Advanced processing schemes consume large quantities of hydrogen. Whether the hydrogen demand will match the quantities of residue available will of course depend on overall refinery configuration. Methanol, either as a direct fuel additive or as a feedstock for MTBE production, can account for utilization of some additional residues. Ammonia prices are too low to make it attractive, and there is no marketing synergy as might be the case with methanol. Speciality chemicals do not generate sufficient volumes to make any impact on the residue problem, although a sidestream unit on a base plant might offer possibilities for a high margin investment. The market for electrical power is acquiring increasing importance as another possibility for absorbing the quantities of residue available [178].

The block flow diagram (Fig. 71) illustrates the plant arrangement for the simultaneous production of all three main products indicated above — power, hydrogen, and methanol — together with the possibility of manufacturing pure carbon monoxide as well. Although, in practice, a plant would rarely be required for all four products, two product schemes are by no means uncommon.

Figure 71. Block flow diagram of an SGP-based methanol and hydrogen plant

SGP = Shell gasification process; SARU = Soot ash removal unit; PSA = pressure swing adsorption

Gas Production. The feedstock is gasified in the SGP reactor (a) with oxygen to produce raw synthesis gas at about 1300 °C and 60 bar (Fig. 72). This gas is a mixture of hydrogen and carbon monoxide, which also contains CO_2, H_2S, and COS together with some free carbon and ash from the feedstock.

Figure 72. Flow diagram of an SGP unit based on residual oil

a) Reactor; b) Waste-heat exchanger; c) Quench pipe; d) Carbon separator; e) Scrubber; f) Soot ash removal

Recovery of the sensible heat in this gas is an integral feature of the SGP process. Primary heat recovery takes place in a waste-heat exchanger (b) generating high-pressure saturated steam in which the reactor effluent is cooled to about 340 °C. The waste-heat exchanger is of a special design developed specifically for these operating conditions. Part of the steam thus generated is used for feedstock and oxidant preheating; the remainder is superheated for use in the CO shift conversion and in steam turbine drives. Steam conditions are chosen to be optimized with the steam turbine part of the combined cycle.

Particulates are removed from the gas by means of a two-stage water wash. Carbon formed in the partial oxidation reactor is removed from the system as a carbon slurry together with the ash and the process condensate. This slurry is subsequently processed in the ash removal unit (f) described below. The product synthesis gas leaves the scrubber at a temperature of about 40 °C and is essentially free of carbon. It is then suitable for treatment with any commercial desulfurization solvent.

Gas Treatment (⟶ Gas Production – Gas Treating). Selection of the actual process to be used for desulfurization depends on the application and on site-specific conditions. The very high purity required for methanol synthesis gas (S<0.1 ppm) practically mandates the Rectisol process, which uses cold methanol as a solvent. For power applications, the high H_2S – CO_2 selectivity of the Purisol solvent *N*-methyl-2-pyrrolidone (NMP) makes it a good choice. Where low investment costs have priority over reduced operating costs methyldiethanolamine (MDEA) may be used. In all cases, the desulfurized gas is suitable for firing in a gas turbine as part of an integrated gasification combined cycle (IGCC) power plant (⟶ Gas Production – Combined Cycle Power System Based on Coal).

The remaining gas is then subjected to CO shift conversion using steam to convert the CO to CO_2 and hydrogen. Hydrogen purification to >99 % can be effected by pressure swing adsorption (PSA) as shown in Figure 71, either with or without prior CO_2 removal. An alternative scheme of CO_2 removal followed by methanation produces a 98 % pure H_2 product with <10 ppm carbon oxides.

A side stream of gas is bypassed around the shift unit to achieve the correct H_2 : CO ratio for the methanol synthesis process. Methanol synthesis itself operates at about 80 bar using the Lurgi Low Pressure Methanol Process followed by a distillation step to achieve the required product quality specification.

The provision for carbon monoxide production is shown by the dotted line in Figure 71. CO_2 is removed to a greater extent than for hydrogen or methanol production before the gas enters the cold box of the cryogenic unit. This produces a CO product that meets the specification for acetic acid production and a >97 % hydrogen stream at about 22 bar. Depending on the overall hydrogen scheme, this may be recompressed and fed through the PSA for final cleanup or used raw in the

refinery.

Side-Stream Units. Wash water from particulate removal is treated in the soot ash removal unit described in more detail below. Carbon and ash are separated from the water by filtration. The filter cake is worked up by controlled oxidation to a salable vanadium concentrate. The bulk of the water is recycled to the water wash.

When using a physical wash such as Rectisol or Purisol, the regeneration system of the desulfurization solvent can be designed to operate selectively so that it produces a gas of sufficiently high H_2S content to allow it to be processed to elemental sulfur in the sulfur recovery unit. In many instances, the Lurgi Oxygen Claus technology (⟶ Sulfur) can be used at this location, either to de-bottleneck existing units or for new plants.

Process Refinements. Handling the carbon slurry is an important aspect of partial oxidation processes. The traditional approach to handling the carbon slurry was to contact it with a hydrocarbon to retain the carbon, which could thus be recycled to the reactor. The early Shell units used fuel oil as the extraction medium (⟶ Gas Production). This allowed atmospheric operation, providing a plant with low investment costs and, at least initially, low operating costs as well. The economics of this approach deteriorated with heavier feedstocks. The pelletizing oil had to be purchased at a premium to the main feedstock, and with higher ash contents, 100 % carbon recycle became nearly impossible since much of the ash was recycled as well.

The logical development of the process was to use naphtha as extraction medium. Soot is extracted from water with naphtha in the form of pellets. These naphtha – soot pellets are sieved off from the water and then mixed in with the main feedstock at whatever temperature is required to achieve the desired viscosity. The naphtha is then distilled off from the feed and recycled to the extraction stage leaving the soot behind in the feed. The use of naphtha as an intermediate allowed the use of heavier, more viscous feedstocks than in the case of pelletizing with fuel oil. Also, improvement in the separation of carbon and ash allowed 100 % recycle. Nonetheless, an ash buildup factor of about 3 : 1 can be observed under 100 % carbon recycle conditions. The plant is costlier than fuel oil pelletizing in both investment and operation.

These facts have led to the review and finally the development of an alternative approach and in particular the possibilities of recovering vanadium for metallurgical use. Figure 73 illustrates the principles of the soot ash removal unit. The carbon slurry from the SGP unit is flashed to atmospheric pressure in the slurry tank (a). The slurry is then filtered on an automatic filter (b) to recover a filter cake with about 80 % residual moisture and a clear water filtrate. The filter cake is subjected to a controlled oxidation process in a multiple-hearth furnace (c). This type of furnace, which is well established in many industries and specifically in the vanadium industry, allows combustion of the carbon to occur under conditions where the vanadium oxides neither melt nor corrode. This is not an easy task if one considers the problems of burning a high-vanadium fuel oil in a conventional boiler. The product is a vanadium concentrate, which contains about 75 % V_2O_5. Compared to the old naphtha extraction-based recycle system, the new once-through process consists of only two processing steps, which are not integrated with the gasification section of the unit. It is cheaper both in investment and in operating costs.

Figure 73. Flow diagram of a soot ash removal unit

a) Slurry tank; b) Filter; c) Multiple-hearth furnace; d) Return water vessel; e) Wastewater stripperSGP = Shell gasification process; SRU = Soot removal unit

An additional benefit of this development is increased feedstock flexibility, both for the SGP itself and for the refinery as a whole. The carbon recycle currently practised also recycles some of the ash, so that the charge pump, burner, and reactor system are exposed to a higher content of ash than that present in the fresh feed. Elimination of the recycle thus makes it possible to use feeds with considerably higher ash contents than previously. Current experience of >1000 µg/g vanadium at the reactor inlet would be directly applicable to residues of this quality. This is certainly an important feature when reviewing the possibility of introducing heavier (and cheaper) crudes into the refinery.

Environmental Aspects. This article has concentrated on the SGP as part of an overall refinery modernization project. Evaluation of the environmental impact can, however, be performed only in the context of such a plant. The data in Tables 3 and 4 are taken from [179] which describes the project under construction in the Shell refinery in The Netherlands.

Table 3. Refinery mass balance, 10^6 t/a

Mass balance	Before 1993	After 1997
Feedstock		
High-sulfur crude	11.3	15.0
Low-sulfur crude	4.5	2.8
Other feedstocks	2.1	0.1
Total intake	17.9	17.9
Production		
White product make	12.8	14.0
Fuel oil make	3.5	2.1
Sulfur	0.11	0.30

Total output	16.4	16.4

Table 4. Refinery and global emissions, 10^3 t/a

Emissions	Before 1993	After 1997
Refinery emissions		
SO_2	35	24
NO_x	12	7
Particulates	4.0	1.9
CO_2	5 000	6 100
Global emissions (refinery + products)		
SO_2	348	206
CO_2	56 600	56 800

The refinery mass balance of Table 3 shows a decisive shift to high-sulfur crude in the future increasing the total intake of high-sulfur crudes from 63 to 84 % of total feed. Nonetheless, the refinery SO_2 emissions and the sulfur content of products are both reduced by one-third, as can be seen in Table 4. Similar reductions can be seen for NO_x and particulate emissons. CO_2 emissions from the refinery increase, but because of the lighter product slate, global CO_2 emissions are hardly affected. All this is achieved with an increase in the high-value white product from 78 to 85 % of total output and a reduction of 40 % in fuel oil output.

The technology described has been applied in a number of refineries as a means of manufacturing chemicals from low-value feedstocks. With increasing environmental awareness and continued refinement of the technology, it is now finding a strategic place in the planning of low- or even zero-residue refineries [180-182].

2.2.12. *Neutral Salt Splitting with the Use of Hydrogen Depolarized Anodes (HydrinaTechnology, Example from De Nora Permelec)*

General. Worldwide, more than 3×10^6 t of sodium sulfate is obtained per year as a byproduct of many industrial processes: only a portion of this production can be commercialized after crystallization and calcination, e.g., for the detergent and glass industries, which, however, have been progressively reducing their consumption in the last ten years. The remaining portion of sodium sulfate is usually diluted and led into the bulk of effluents or disposed of.

However, disposal will become increasingly difficult, if not impossible, in the near future due to tighter environmental regulations. In any case, it will certainly become increasingly expensive and for this reason, at least, the recovery by electrolysis of sodium sulfate — and in general of other neutral salts, such as sodium nitrate and sodium chloride, which are also generated in some chemical processes — is expected to have a bright future.

The overall economics of the recovery of byproduct salts by electrolysis benefits from the saving of the disposal cost as well as from the production of caustic and acid, which may be recycled to upstream plants. The success of this operation depends on a number of conditions including

1. Substantial savings of money, which otherwise would have been required for disposal of byproduct salts. In the specific case of sodium sulfate, electrolysis becomes economically interesting when the disposal cost of the salt is in the order of $ 100 per tonne, with a caustic soda price in the range of $ 200 per tonne.
2. Electric energy consumption per tonne of produced caustic soda, which is close to that of membrane chlor – alkali electrolysis (i.e., 2200 – 2500 kW · h/t).
3. Simple and reliable integration with the plants where the byproduct salts are generated. This integration may require auxiliary sections designed to eliminate impurities, to concentrate byproduct salt solutions when these are excessively dilute, (e.g., <10 wt %), and, in some cases, to concentrate the acid produced.
4. Negligible requirements of manpower for both operation and maintenance.

Structure of the Electrolyzers (see also ⟶ Electrochemistry). The following discussion is based on sodium sulfate, which is the byproduct salt of greatest concern [183], [184]. However, many of the conclusions also apply to the electrolysis of other salts such as potassium sulfate and sodium and potassium nitrate.

Industrial electrolyzers are made of rows of electrically connected elementary cells, preferably of the bipolar type. Many elementary cell structures have been described in the literature. The most important from the industrial point of view are:

1. Elementary cells comprising two compartments separated by a cation-exchange membrane (MC), as illustrated in Figure 74, to produce caustic soda and a mixture of sulfuric acid and unconverted sodium sulfate, hydrogen, and oxygen.
2. Elementary cells comprising three compartments separated by two membranes, namely a cation-exchange (MC) and an anionexchange (MA) membrane (see Fig. 75). In this case the electrolysis products are caustic soda,

sulfuric acid, hydrogen, and oxygen.

3. Elementary cells comprising three compartments separated by two cation-exchange membranes as illustrated in Figure 76. In this case, the products are again caustic soda, a mixture of sulfuric acid and unconverted sodium sulfate, hydrogen, and oxygen, as in the case of the two-compartment process. The additional anodic compartment acts as a buffer section so that the solution to be electrolyzed is separated from the anode. This scheme is particularly useful to prevent:
   - Anodic side reactions, as in the presence of certain oxidizable anions, such as chlorate [185]
   - Corrosion of the anodes due to the high concentration of sulfuric acid and unconverted sodium sulfate at elevated temperature
   - Decay of the membranes caused by large contents of impurities in the feed solutions [186]

Figure 74. Flow diagram of sodium sulfate electrolysis in two-compartment electrolyzers (production of acid sodium sulfate, oxygen-evolving anodes)

MC = Cation-exchange membrane

Figure 75. Flow diagram of sodium sulfate electrolysis in three-compartment electrolyzers (production of pure sulfuric acid, oxygen-evolving anodes)

MC = Cation-exchange membrane; MA = Anion-exchange membrane

Figure 76. Flow diagram of sodium sulfate electrolysis in three-compartment electrolyzers (buffer compartment)

MC = Cation-exchange membrane

A problem affecting all three schemes is the high cell voltage, which involves high energy consumption. The high cell voltage results from the energy required to perform the following reaction at an industrially useful rate:

$$Na_2SO_4 + 3\,H_2O \rightarrow 2\,NaOH + H_2SO_4 + H_2 + 0.5\,O_2$$

Energy consumption may be substantially reduced by replacing the oxygen-evolving anode with a hydrogen depolarized anode [186], [187]. The modified schemes are shown in Figures 77 and 78.

Figure 77. Production of acid sodium sulfate in the Hydrina membrane electrolyzer

MC = Cation-exchange membrane; DAP = Depolarized anode package

Figure 78. Production of pure sulfuric acid in the Hydrina membrane electrolyzer

MC = Cation-exchange membrane; MA = Anion-exchange membrane; DAP = Depolarized anode package

The energy consumption is decreased remarkably according to the following new overall reaction:

$$Na_2SO_4 + 2\,H_2O \rightarrow 2\,NaOH + H_2SO_4$$

Figures 77 and 78 demonstrate that the hydrogen consumed at the depolarized anode is the same hydrogen evolved at the corresponding cathode. This hydrogen need only be washed in a suitable scrubber to eliminate entrained catholyte mists. The hydrogen thus obtained has a high purity, which allows for long-term stability of the catalyst of the depolarized anode.

A conventional structure used for the hydrogen depolarized anode consists of an electrically conductive sheet with controlled porosity and hydrophobicity, coated with a catalytic layer. Under optimum operating conditions the electrolyte partially fills the pores, with the gas –liquid meniscus in the area of the sheet containing the catalyst.

Operating conditions causing percolation of the electrolyte through the pores or loss of gas in the electrolyte should be avoided. For this reason, anodes of this type allow rather small pressure differentials between the electrolytic compartment and the hydrogen chamber. The height of these anodes is thus limited. Thus, cell designs with segmented compartments have been proposed [188]. Besides this limitation, conventional electrodes are affected by problems caused by the presence of electrolyte in the pores in direct contact with catalyst. Therefore, both crystallization phenomena are experienced, which result in destruction of the porous sheet structure and poisoning of the catalyst when the electrolyte contains heavy metals, even in trace amounts.

These problems are overcome by using a depolarized anode made of a porous sheet containing a catalyst, bonded or pressed against a cation-exchange membrane [189-191]. The assembly formed by the membrane and the porous catalytic sheet is in turn bonded to or pressed against a suitable porous current collector, such as an expanded metal or wire mesh. The dimensions of the voids in the expanded metal or wire mesh are preferably small in order to allow simultaneously good mechanical support of the membrane – porous sheet assembly and homogeneous current distribution.

The current collector is made of a material that resists the corrosive action of sulfuric acid, which may contact the collector in the event of a discontinuity in the membrane, such as a pinhole or crack, formed during fabrication, handling, or operation. Suitable materials capable of operating at 60 – 70 °C are nickel alloys. With optimized assemblies (DAP, De Nora Permelec, Milan, Italy), overall anodic overvoltages of 0.1 – 0.2 V at 3000 A/m^2 are obtained.

In the bipolar arrangement of elementary cells the following overall reaction occurs in the separation wall between the depolarized anode and the cathode:

$$H_2O \rightarrow H^+ + OH^-$$

which is the same reaction occurring in bipolar membranes for electrodialysis [192]. In particular, the overall reaction results from an anodic partial reaction:

$$H_2 - 2e^- \rightarrow 2H^+$$

which takes place in the acid environment of the ionic groups of the cation-exchange membrane and a cathodic partial reaction:

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^-$$

which occurs in the alkaline environment of the catholyte made of caustic soda.

When the cathode is provided with an electrocatalytic coating, the overall voltage across the bipolar separation wall between two adjacent cells has the remarkably low value of 1.2 – 1.3 V at 3000 A/m^2, thus equal to or even lower than that of bipolar membranes at 1000 A/m^2 [193].

The outstanding performance at high current densities largely counterbalances the intrinsically higher cost of the structure comprising the hydrogen depolarized anode, bipolar wall, and activated cathode as compared with bipolar membranes. Further advantages of the assembly are the long service life due to the mechanical strength, a low sensitivity to impurities contained in the feed electrolyte, and high quality of the products.

Operating Conditions. Voltage vs. current relationships for three types of cells provided with DAP, electrocatalytic cathodes, electrolytic compartments having 3-mm gaps, and turbulence promoters are given below:

Voltage (V) – current density (CD) relationships for three internal structures of the elementary cell for sodium sulfate electrolysis:

1. Two-compartment, cation-exchange membrane V = 0.96 + 0.59×CD (kA/m^2)
2. Three-compartment, cation- and anionexchange membranes V = 0.97 + 1.02×CD (kA/m^2)
3. Three-compartment, two cation-exchange membranes (buffer compartment) V = 0.98 + 0.89×CD (kA/m^2)

The three relationships apply to current densities up to 3000 A/m^2. The DAP assembly comprises a hydrogen depolarized anode and a Nafion 117 membrane; the electrolytic compartments are limited by Nafion 324 and Selemion AAV ionexchange membranes. The relationships further apply to operating temperatures of 60 – 70 °C and to 13 – 18 % caustic soda, 200 – 300 g/L sodium sulfate, and 10 % sulfuric acid.

The current efficiency for the production of caustic soda (“cathodic efficiency”) is a complex function of the following factors:

1. *Caustic soda concentration*
   Other conditions being the same, the cathodic current efficiency decreases as the caustic soda concentration increases to more than 15 – 18 %.
2. *Molar ratio (MR) between sulfuric acid and sodium sulfate at constant sodium sulfate concentration*
   The second dissociation constant of sulfuric acid is rather low, in the range of 0.01. Consequently, in a solution

containing both sulfuric acid and sodium sulfate at MR <1, substantially all the sulfuric acid reacts with the stoichiometric amount of sodium sulfate to give sodium bisulfate (buffer action). Hence, the actual concentration of free protons (H^+) is directly proportional to the actual concentration of sodium bisulfate and inversely proportional to that of the unreacted sodium sulfate. This type of dependence indicates that the actual concentration of free protons should increase quickly when MR exceeds a certain critical value (ca. 0.5). At higher MR values the current transported by the protons becomes significant at the expense of that transported by the sodium ions, and the cathodic efficiency shows a sharp decrease.

3. *Sodium sulfate concentration at constant MR* At MR values <1, the proton concentration, which is a function of the ratio MR to (1 – MR), is expected to remain constant at constant molar ratios, even if the concentrations of both sulfuric acid and sodium sulfate are greatly changed. Consequently, the transport number of the protons decreases as the concentration of sodium sulfate (i.e., the concentration of sodium ions) is increased. At the same time, the cathodic current efficiency increases.

This behavior has also been discussed in terms of alkaline state (to the left of the critical point of MR) and acid state (to the right of the critical point) of the cation-exchange membrane [187], [194]. This difference in internal states of the membrane is connected to the presence in the conductive channels of the membrane of a population of either hydroxyl ions (back migration from the catholyte when the electric current is substantially transported by sodium ions; low MR values) or protons (significant portion of the current transported by protons; high MR values). The model has remarkable practical consequences, particularly in terms of the sensitivity of the membrane with respect to impurities contained in the feed solutions.

The above considerations also apply to other salts that derive from weak acids, such as phosphates, acetates, and in general the sodium salts of many organic acids. The behavior of salts deriving from strong acids, such as nitrates, chlorates, and perchlorates, is substantially different because these salts are not able to perform any buffer action. Thus, at a given cathodic current efficiency, the allowed concentration of acid is significantly lower than that typical of sodium sulfate solutions. The concentration of acid can, however, be increased by the addition of a “dead load” of sodium sulfate, which creates the necessary buffer action [195].

With two-compartment cells the cathodic efficiency also represents the total current efficiency of the process. In the three-compartment cells, the current efficiency for sulfuric acid production (anodic efficiency) must also be taken into consideration. The overall current efficiency of electrolysis is represented by the lower of the two efficiencies. If, for example, the anodic efficiency is lower than the cathodic, acidity builds up in the sodium sulfate compartment during operation so that the cathodic current efficiency progressively decreases; when it reaches the same value as the anodic, stationary process conditions are maintained. Therefore, the process is provided with a self-regulating mechanism. Alternatively, if the accumulation of acidity in the sodium sulfate compartment cannot be allowed, then a portion of the caustic soda produced can be fed into the sodium sulfate loop. The quantity of caustic soda available for use outside the electrolysis plant again represents the overall current efficiency, which still remains a function of the anodic efficiency. The anodic and cathodic current efficiencies can be made independent when the control of acidity in the sodium sulfate compartment is performed by means of sodium carbonate addition.

Auxiliary Sections. The electrolysis plant may contain auxiliary units necessary for functional integration with the upstream plants where sodium sulfate is generated and the electrolysis products are fed back.

Treatment of Sodium Sulfate Feed. Impurities normally present in the sodium sulfate feed are Ca, Mg, Al, and Si. These impurities penetrate into the cation-exchange membranes separating the sodium sulfate and the caustic soda compartments; they react with the internal alkaline environment and precipitate, causing a voltage increase and a loss of cathodic efficiency.

Internal precipitation is less likely when the caustic soda contained in the cathodic compartment is diluted. With caustic soda concentrations in the range of 10 – 15 %, the total concentration of impurities may reach a maximum value in the order of 1 – 5 µg/g, depending on the type of membrane [183]. If the membrane is operated in the acid state [187], [194], this limit of concentration may be increased to 20 – 30 µg/g [187], [196]. Obviously, this is a compromise, because the advantage of operating under safe conditions for the membrane (even in the presence of relatively high impurity concentrations) is counterbalanced by the lower cathodic current efficiency typical of the acid state of the cationexchange membranes.

These general considerations must, in any case, take into account both the kind of electrolysis and the structure of the cells (two or three electrolyte compartments). In the first case, the sulfate solution is strongly acid and high levels of impurities are allowable. Besides, the electrolysis cell is inserted in an open cycle where the accumulation of impurities is negligible.

In the second case, the cell is inserted in a substantially closed loop. This situation leads to the accumulation of impurities. In this case, a chemical purification unit must be introduced, which, in its simplest form, may be quite similar to the primary treatment of chlor – alkali plants. The treatment is based on additions of caustic soda and sodium carbonate followed by filtration, and it allows the concentration of impurities, such as calcium and magnesium, to be kept in the range of 1 – 5 µg/g. The additional investment required for chemical treatment is rather limited as are the operational costs.

Chemical treatment may be replaced by crystallization or ion-exchange units. However, their investment and operating costs are substantial and negatively influence the economics of the entire process. In addition, crystallization and ion exchange are delicate operations that may require specialized personnel.

Concentration of Sodium Sulfate Solutions. A concentration unit is always necessary for both two- and three-compartment cells when the feed consists of dilute sodium sulfate solutions, because the cell voltage increases rapidly when the sodium sulfate concentration is <10 %. The methods available are reverse osmosis, electrodialysis, and evaporation. With the

present average European prices of steam and electric energy, evaporation seems to be the best method for concentrating up to 20 % diluted feed solutions having a salt content around 3 – 5 %.

Even if the feed solutions are concentrated (e.g., to ca. 20 %), evaporation is still required when electrolysis is carried out in three-compartment cells. In this case, evaporation is directed to keep constant the amount of water in the electrolysis section. Water is let in with the feed solution and only partially migrates through the cationic and anionic membranes to form caustic soda and sulfuric acid.

Obviously, evaporation is not required when the makeup consists of solid salts. The evaporation unit is expensive with respect to both investment and operating costs, and its installation should be the object of careful economic analysis.

As a purely indicative example, an electrolysis plant based on three-compartment cells is considered, having a capacity of 3000 t/a of sodium sulfate (100 % basis) fed to the cells as a 20 % solution: The investment for a doubleeffect evaporation unit represents about 10 – 15 % of the total investment for the complete plant, comprising cells, rectifier, pretreatment unit, evaporation, and construction. The cost of steam amounts to about 50 % of the total electric energy cost.

Clearly, the energy consumption, which is already substantial for the 20 % feed solution, increases sharply as the feed solution becomes more dilute.

Before beginning an economic analysis to define the most convenient trade-off between evaporation and electrolysis cost, the upstream plants where sodium sulfate is generated should be inspected carefully to determine whether the dilute solutions are formed as such or are the result of mixing with other process wastewaters. Internal dilution is often a consequence of the old attitude toward byproduct salt solutions, which were diluted as much as possible within the battery limits of the plants to reach the limit allowed for discharge.

Sulfuric Acid Concentration. In three-compartment electrolysis, 10 to 15 wt % of pure sulfuric acid is produced with an anodic efficiency in the range of 60 – 75 %. Often these solutions are too dilute to be fed directly to upstream plants. This requires concentration by evaporation, which, however, may be limited to a maximum concentration of 75 wt %. A unit of this type with an annual capacity of ca. 2000 t of acid (100 % basis) involves an investment that amounts to about 15 – 20 % of the total investment required for the complete plant. The steam consumption for a double-effect unit, at current European prices for electric energy and steam, corresponds to about 30 % of the electrical energy cost of electrolysis.

Conclusions. The Hydrina technology developed by De Nora Permelec for low-cost splitting of neutral salts has the following advantages:

1. Easy integration of the electrolysis process into the production cycle, thereby forming a “closed loop”
2. Transformation of byproducts into valuable chemicals such as caustic soda and acid
3. Elimination of any environmental problems deriving from the disposal of byproduct salts

2.2.13. *Ultrapure Isopropanol Purification and Recycling System (Example from Mitsubishi Chemical)*

Background of Isopropanol Recycling System. In the electronics industry, ultrafine pattern processing technology for greater-capacity devices has been developed. This technology requires complete exclusion of impurities from the manufacturing lines, i.e., a highly sophisticated clean room technique, and highly purified water and solvents among other measures.

One of the solvents used in ultrafine pattern processing technology is ultrapure isopropanol (IPA), which is widely used in vapor dryers for drying the electronic devices and liquid crystal display substrates that have been washed with ultrapure water [197-199]. At present, the large amount of used IPA — containing impurities such as water, metal ions, and particles — is discarded after use. When using IPA, the following serious problems arise:

1. Increase in production costs through the use of large quantities of ultrapure IPA that are not recycled
2. Latent danger of using a large amount of flammable liquid
3. Environmental problems because of the large quantities of waste IPA that are disposed of

To solve these problems, the new IPA purification and recycling system has been developed, which can reproduce ultrapure IPA that meets the specifications of the electronics industry from the waste IPA. This system is composed of a high-performance dehydration unit based on pervaporation membrane separation; a metal-ion elimination unit based on distillation; and a particle elimination unit based on microfiltration. These units remove each impuritiy efficiently from waste IPA, and purified IPA can be recycled to manufacturing processes of the electronics industry.

Pervaporation Membrane Separation. Pervaporation (PV) is a membrane process to separate the components of liquid mixtures (⟶ Membranes and Membrane Separation Processes – Principle of Pervaporation); a liquid mixture is fed to one side of a membrane, permeating as vapor to the opposite side to which a vacuum or sweeping gas is typically applied (see Fig. 79). This nonequilibrium process is regarded as a suitable alternative process for the separation of organic liquid mixtures such as azeotropic mixtures, mixtures having close boiling points, mixtures of structural isomers, and of heat-sensitive organic compounds. Pervaporation has been commercialized for the separation of water from concentrated alcohol solution, primarily ethanol (⟶ Ethanol) and IPA. Other applications, such as separations of small amounts of organic solvents from contaminated waters and separations of purely organic mixtures, are under development.

The most widely accepted model for describing the transport mechanism through the pervaporation membrane is a modified solution – diffusion model, where a permeating component is first dissolved or adsorbed in the membrane and then transported through it by a diffusion process. In this process, separation of the mixture is achieved by differences in the solubility and diffusibility of the individual components.

Performances of PV membranes are represented by parameters such as separation factor, flux of permeates, and service life. The separation factor of a membrane is a measure of its permeation selectivity (permselectivity) and is defined as the ratio of the concentration of components in the permeate mixture to that in the feed mixture. The component flux is the amount of a component permeating per unit time and unit area, and is given by the product of the permeability coefficient of the membrane and the driving force. The driving force is the gradient in the chemical potential of the components between the feed and the permeate side of the membrane. These values are influenced by operating variables such as temperature, composition of each component in the feed mixture, and permeate side pressures (see Fig. 80).

Figure 79. Flow sheet of the pervaporation process

Figure 80. Mass-transfer model for pervaporation of an IPA – water mixture

J_W = Flux of water; J_i = Flux of IPA; Q_W = Permeation coefficient of water; γ_W = Activity coefficient of water; P_{0W} = Saturated vapor pressure of water at operating temperature; P_{1W} = Partial pressure of water on feed side; P_{2W} = Partial pressure of water on permeate side; P_2 = Total pressure on permeate side

Separation of IPA and Water by Pervaporation. In the PV membrane separation unit, the water permselective membrane is used for dehydration. Water in the feed mixture can permeate through the membrane; the IPA, in contrast, effectively cannot. Consequently, the residue IPA on the feed side is dehydrated.

The water concentration of the feed side decreases as dehydration progresses and lowers the chemical potential of water on the feed side. This means that a greater degree of dehydration requires a higher operating temperature to increase the driving force. The low heat resistance of conventional membranes has up to now prevented PV separation processes at high temperature [200], [201]. In contrast, the novel heat-resistant membrane used in the IPA – water system enables the operation to be performed at higher temperature, achieving not only the high degree of dehydration but also the large water flux and increasing total system performance (see Fig. 81).

The permeate water vapor is continuously condensed in a cooler, stored in a tank, and discharged. Due to the superior permselectivity of the membrane, the amount of IPA in the permeate mixture becomes very small; therefore, the IPA load of the wastewater decreases significantly.

The membrane is in the form of a hollow fiber (see Fig. 82), which has the advantage of reduced outer dimensions together with a large membrane area. The membrane module consists only of the hollow fiber bundle and the module housing. Such a simple structure can avoid difficulties encountered with other membrane module designs, such as sealing of flat seat type and spiral-wound type membranes and furthermore can reduce not only the volume and the weight of the modules, but also the total system size.

Figure 81. Relationship between difference in partial pressure of water and flux of water

Figure 82. Structure of the pervaporation module

a) Fiber bundle; b) Module housing

Distillation Unit and Filtration Unit. In this system, purification and recycling of IPA is performed by the combination of the PV membrane dehydration unit, the distillation unit, and the microfiltration unit. In the distillation unit, impurities, which are difficult to separate in the PV membrane separation unit such as dissolved metal ions and high-boiling impurities, are completely eliminated.

In the last process step, fine particles are removed by the microfiltration unit. In the manufacture of highly integrated electronic devices, particles from the solvents used in these processes must be removed to improve product yields and suppress wafer contamination defects. For example, particles with >0.05-µm diameter should be removed to the extent of less than 10 particles per milliliter from solvents used in 16-Mbit level production lines [202]. Accordingly, the level of the microfiltration unit affects total system performance; therefore, the unit should be equipped with an appropriate filtration membrane, although only a few membranes with sufficient performance are available [203]. In the solvent a very low level of dissolved metals and low total organic carbon (TOC) is desired. Moreover, high chemical resistance of the filtration membrane is also needed.

The system can vary the required capacity by a change in its composition. For example, if the 90 % IPA makeup solution could be purified up to 99.9 % IPA concentration with a feed rate of 12 kg/h, then more than 10 kg/h of product would be obtained. The number of particles with diameter of >0.2 µm is less than 10 particles per milliliter product. The metal ion content of the product is ≤1 ppb (i.e., 1 µL/m^3) for the following elements:

Al	Ca	Cu	Mg	Pb
As	Cd	Fe	Mn	Sn
B	Co	K	Na	Sr
Ba	Cr	Li	Ni	Zn

These results were achieved by using S 111 and M 111 type purification/recycling systems; the dimensions (mm) of the systems are 600, 2300 width, 1700 height and 800 depth, 2300 width, 1460 height respectively, and the masses of both systems are 500 kg. A schematic of the entire unit is shown in Figure 83.

2.2.14. *Examples from Boehringer Mannheim*

2.2.14.1. *Biocatalytic Splitting of Penicillin [204]*

Introduction. The technique of biocatalysis has been used for thousands of years in the production of various food products including bread (“sourdough”); the fermentation of sugar from fruit and fruit pulp to produce alcoholic beverages; the processing of milk to produce cheese, yoghurt, and other products; the production of vinegar and sauerkraut; and many other products.

These processes utilize the activity of biological catalysts (enzymes), which are formed by bacteria, yeasts, and molds. Each individual enzyme performs a different biocatalytic function.

A particularly successful and technically elegant biocatalytic process is the conversion of natural penicillin into a product that is necessary for the production of chemically modified penicillins. This product, known as 6-aminopenicillanic acid, is formed by splitting off the side chain of penicillin.

6-Aminopenicillanic acid is treated to obtain the so-called semisynthetic penicillins, of which the most well known are ampicillin and amoxycillin (see below).

The enormous importance of penicillins in combating infections is shown by the fact that >4000 t/a of 6-aminopenicillanic acid alone is produced.

Today, by use of genetic engineering, the active enzymes can be obtained relatively simply and selectively in pure form.

By immobilizing these in a porous matrix, they can be converted into a form with very convenient properties for technical handling purposes (⟶ Immobilized Biocatalysts – Methods of Enzyme Immobilization).

In the biocatalytic process for splitting penicillin described here, genetically engineered penicillin amidase is used, which is bonded to polymer particles the size of sand grains.

This process has almost completely superseded an older chemical process, over which it has a number of advantages including a better environmental balance:

1. Lower production costs
2. Energy savings
3. Fewer safety problems
4. Fewer disposal problems
5. Improved product quality

Comparison of the Environmental Balance of the Chemical and Bioctalytic Processes. The reason for the *reduction in production costs* is immediately apparent from the reaction sequence shown in Figure 84. Whereas the chemical process requires three intermediate stages, the biocatalytic process occurs in a single synthesis step in water at room temperature with ammonia addition for neutralization.

Figure 84. Reaction scheme for chemical and biocatalytic splitting of penicillin

The advantages of the biocatalytic process are impressive if the conversion of 1000 t penicillin is considered; this yields ca. 500 t product or slightly less than one-eighth of annual world production (see below).

Chemical method	**Biocatalytic method**
Consumption of reagents	
1000 t Penicillin G, potassium salt	1000 t Penicillin G, potassium salt
800 t *N,N*-Dimethylaniline	
600 t Phosphorus pentachloride	
300 t Dimethyldichlorosilane	
160 t Ammonia	45 t Ammonia
	0.5 – 1 t Biocatalyst
Consumption of solvents (recoverable, partly for disposal)	
4200 m^3 Dichloromethane	10 000 m^3 Water
4200 m^3 Butanol	
Product isolation and purifiction	
Acetone	Acetone
Ammonium bicarbonate	Butyl acetate
	Hydrochloric acid
Energy consumption (estimated from cooling costs)	
6×10^6 kW · h	3×10^6 kW · h

The potential *energy savings* can be estimated from the much reduced cooling costs. Whereas the chemical process requires a temperature of –50 °C, the biocatalytic process is carried out at 28 – 35 °C. Thus, expensive cooling is replaced by comparatively cheap heating.

The absence of highly reactive chemicals in the biocatalytic process reduces the complexity of *safety measures*, which would otherwise be considerable. Phosphorus pentachloride especially poses a problem, because it must be stored and handled with complete exclusion of moisture since it is strongly hygroscopic and decomposes with the liberation of hydrogen chloride gas.

In the biocatalytic process, waste gas purification is not necessary, and no *disposal problems* involving environmentally harmful chlorine-containing solvents or byproducts from the synthesis process occur.

In the bioctalytic process, the *product quality requirements* are considerably easier to comply with. In the old process, *N,N*-dimethylaniline had to be removed from the reaction product, because this toxic substance may be present only below its toxicity threshold (i.e., in extremely small traces).

The absence of significant quantities of environmentally problematic substances and the large contribution to energy savings reflect the enormous potential of biocatalysis for solving and preventing environmental problems.

2.2.14.2. *Production of Diagnostic Reagents by Means of Genetic Engineering: Glucose-6-Phosphate Dehydrogenase and α-Glucosidase [204]*

Introduction. Diagnostic reagents are important tools for medical investigations (⟶). For some of these (e.g., the testing of blood and other bodily fluids), chemical reactions are no longer used; biochemical methods based on enzymes are preferred.

Glucose-6-phosphate dehydrogenase (G6PDH) (E.C. 1.1.1.49) is used in diagnostics to determine the glucose content of serum (⟶), and *α-glucosidase* is used in a test combination for the determination of amylase content, an important parameter in determining the functional capability of the human pancreas. High-purity enzymes in kilogram quantities are required for the enormous number of laboratory investigations conducted.

Conventional biochemical processes require up to 1000 t of biological raw materials to produce 1 kg of an enzyme suitable for bioanalysis.

The efficiency of enzyme production by biotechnological methods can be much improved by genetic engineering (⟶ Genetic Engineering). Reprogramming (cloning) the genetic information of microorganisms that can be grown by simple means (bacteria or yeasts) enables them to produce certain proteins (e.g., enzymes) in excess. By means of recombinant DNA technology, up to 1000 copies per cell can encode the desired protein. In this way, up to 50 % of the total protein in the cell can consist of the desired product. By culturing the genetically engineered microorganisms under special conditions in a medium containing special nutrients, the overproduction of the cell can be utilized technologically. At the same time, large savings in energy and raw materials are made.

Reduction of Environmental Pollution by Production of Glucose-6-phosphate Dehydrogenase and α-Glucosidase by Genetic Engineering. *Production of Glucose-6-Phosphate Dehydrogenase.* The bacterial strain *Leuconostoc* sp., used in the production of G6PDH by the conventional biochemical method, has a volume activity of the desired enzyme of 5.5 U/mL. By cloning the appropriate gene in *Escherichia coli*, an increase in the genetic enzyme yield (genetic expression) to 500 U/mL is obtained even on the 5-mL scale. Optimization of the fermentation process enables a further increase by a factor of 1000 to be achieved, i.e., a genetic expression of 4500 –5000. The savings in raw materials and energy during fermentation alone resulting from using *E. coli* instead of *Leuconostoc* are listed in Table 5.

Table 5. Prevention of environmental pollution by use of recombinant organisms in the producton of G6PDH during fermentation

Quantity	*Leuconostoc*	Recombinant *E. coli*
Fermentation volume, m^3	600	1
Salts and nutrients, kg	64 000	160
Pure water consumption, m^3	120	1
Cooling water consumption, m^3	15 000	30
Amount of O_2-free water required, m^3	740	
Amount of ice water required, m^3	4 800	
Energy requirements for steam production, kW · h	16 000	270
Compressed air, m^3	114 000	570
Wastewater PE* value	300 000	300

* PE = population equivalent (i.e., organic load due to a member of the population over 24 h).

A comparison of the conventional culture process with that using recombinant *E. coli* shows that only 0.1 % of the raw materials and energy of the conventional process is required for the recombinant process. This is true for both the fermentation process and the downstreaming procedure (Table 6).

Table 6. Prevention of environmental pollution by use of recombinant organisms in the production of G6PDH during workup

Quantity	*Leuconostoc*	Recombinant *E. coli*
Biomass, kg	22 000	200
Wastewater, m^3	1 200	0.2
Water, m^3	300	10
Ice water, m^3	4 000	50
Pure water, m^3	300	10

Steam, t	180	10
Electricity, kW · h	4 000	100
Ammonium sulfate, kg	13 000	200

To provide a given quantity of this enzyme, only 200 kg biomass is required when using recombinant *E. coli* instead of 22 000 kg. Savings of a similar order of magnitude are obtained in the areas of energy consumption, steam, water, pure water, and of course, electricity.

The recombinant process gives a saving of ca. 95 – 98 % in raw materials and energy. This leads to a reduction in the load on the sewage treatment plant which is illustrated by so-called population equivalents. A population equivalent (PE) is defined as the organic load due to a member of the population over 24 h. Treatment of this organic load requires 60 g of oxygen. In the production of G6PDH by recombinant organisms, the organic load produced by the fermentation process is equivalent to 0.1 % of that produced by the conventional process. This means that the amount of organic waste to be treated, instead of being equivalent to that from a large town (300 000 PE), is only equivalent to that from several large families (300 PE).

Production of α-Glucosidase. α -Glucosidase can also be produced very effectively using recombinant yeast instead of normal yeast strains (Table 7).

Table 7. Prevention of environmental pollution by use of recombinant organisms in the production of α-glucosidase (1988 consumption figures)

Quantity	Production of α-glucosidase	
	From new yeast	From recombinant yeast
Yeast consumption, t	236	10
Wastewater from yeast production plant, t (ca. 9 t wastewater/t yeast)	ca. 2 000	ca. 90
Quantity of yeast residues for disposal, t	440	12
Ammonium sulfate, t	1 100	25
Potassium phosphate, t	25	0.5
Aluminum gel, t	90	
Filter aids, t	133	5
Solid waste, t	540	18
Liquid waste, t (ammonium sulfate + potassium phosphate as fertilizers)	1 125	25.5
Deionized water, m^3	3 700	50
Ice water, m^3	52 000	2 000
Electric power, kW	44 500	9 000
Steam, t	220	50

The treatment of residues from processes based on genetic engineering (wastewater, decomposed biomass) must be carried out in accordance with the safety requirements of genetic engineering law and genetic engineering safety regulations. The genetically modified microorganisms (*E. coli* and yeast) used in the processes described here are classified in the lowest safety group S 1. The wastewater (fermentation liquors) can therefore be transferred directly to a biological sewage treatment plant. Solid residues (decomposed biomass) can be composted without further treatment.

When using recombinant yeast strains, the amount of biomass to be disposed of is much smaller than with normal yeast strains because the fermentation volume is smaller (i.e., 1.2 t instead of 440 t). The water and energy consumption in the α-glucosidase production process involving genetic engineering is ca. 10 – 20 % of that of the conventional process (Table 7).

About 100 diagnostic products are produced by Boehringer Mannheim in this environmentally friendly way using genetic engineering techniques.

1. Safety Problems in Chemical Plants

1.1. Types and Sources of Hazards

1.1.1. Fundamentals

Large-scale chemical production is one of the most important industrial activities. Its products play key roles in human nutrition, health, quality of life, and welfare. Nevertheless, many people regard chemical production as dangerous, even though chemical processes are associated with accident frequencies which are much lower than in other industries – and very few such accidents have anything to do with chemistry [2].

Despite the good accident statistics of chemical plants, grave accidents have occurred, endangering human life and the environment, and causing considerable damage. The names

Flixborough (1974) [3], Seveso (1976) [4], Bhopal (1984) [5], and Basel (1986) [6] call spectacular events to mind.

Three types of event are traditionally associated with the chemical industry:

Releases and spills (Seveso, Bhopal)
Fires (Basel)
Explosions (Flixborough)

"Explosion" as used here refers to an event in which large amounts of energy are released very rapidly (ultimately, in the form of expansion energy), producing a pressure wave that is (at least) audible and propagates at high velocity, decaying over distance.

Damage caused by the above mentioned three types of event comes about through two distinct processes:

Direct action of chemicals on humans and the environment
Indirect action of liberated energy

In the Bhopal accident, many people died after inhaling a dangerous gas that had escaped from a tank storage facility [5]. Most of the damage from the Basel warehouse fire was due to fire fighting water carrying starting material, decomposition products, and combustion products out of the stored material, harming the ecosystem of the Rhine [6]. The consequences of the Flixborough explosion occurred largely through the destructive action of the pressure wave, initiated by ignition of a cloud of escaped flammable gases [3].

Generally, chemical reactions underlie such harmful effects. When substances act directly on living matter, a chemical reaction may alter or destroy cellular tissue (toxic effect). In an explosion, energy is liberated by an exothermic chemical reaction.

It is obvious that the dangers arising from chemical plants have much to do with the nature of the substances being processed, the way they are treated in the plant, and their tendency to take part in chemical reactions under these conditions.

A conflict arises between process needs and chemical safety. On the one hand, chemistry requires reactive substances; on the other hand, this reactivity of the substances is a key aspect of the danger they pose.

A chemical process is impossible without substances that show hazardous properties and effects. The substances must therefore be reliably contained in the process equipment, and their reactivity must be governed so that uncontrolled chemical reactions cannot take place.

1.1.2. Causes and Effects

Releases and Spills. An uncontrolled release from a closed facility presupposes an undesired opening of the containment (e.g., of a valve), or damage to the walls of vessels, process equipment, fittings, or piping (e.g., as a consequence of corrosion, seal failure, or rupture).

If liquids and solids are released, people outside the plant are, as a rule, not directly endangered (or at worst after some time delay) and they are thus more easily protected. The material, on the other hand, can penetrate into the soil, contaminating the groundwater or passing through sewers into surface waters, posing a danger to the environment. Precautions inside the facility include erection of barriers (liquidproof floors, seals on sewers, and retention systems; see Section 5.1).

If the substances are gaseous or finely dispersed (aerosols), they are transported by the motion of the ambient air after their release, so that they can be spread over large areas, diluted by convection and diffusion, separated from the air by sorption and possibly sedimentation, and gradually degraded through chemical reactions with the environment.

Above certain concentration levels in air, pollutants can harm people, fauna, and flora in downstream regions. The amount of damage depends on the exposure time (dose). Usually, such a drifting gas or aerosol cloud causes a short-term burden on individuals exposed to varying concentrations. Toxicology must provide information about these harmful effects (see Section 2.1).

Explosions. An explosion involves the rapid, almost instantaneous release of heat and expansion energy resulting in the formation of large gas volumes and a (destructive) pressure wave, which propagates at high velocity. At a fixed point, the wave causes a sudden rise in pressure

followed by a pressure drop, all within a fraction of a second.

The pressure wave arises because the volumes of gas formed cannot escape quickly enough by mass motion. The destructive action of the wave results from the pressure force and the rapid transfer of momentum to objects in the region of wave propagation.

Energy-supplying processes in an explosion can be chemical or purely physical. There are three different types of chemical explosion. The best-known is the instantaneous decomposition of sensitive chemical compounds to gaseous species occupying a large volume, because it figures in the use of explosives. The process is initiated by external excitation. The volume required for the gaseous products is markedly increased by the heat of decomposition evolved in the process. Decomposition can be excited mechanically by shear forces (friction) or impact; thermally by heating; or by the chemically generated shock wave from an igniter (see Section 2.2.4).

The second chemical explosion process is also fairly well known: rapid oxidation of gases or finely dispersed particles in oxidizing gases (see Sections 2.2.2, 2.2.3). A highly exothermic reaction (usually combustion) heats the gases to high temperature so quickly that the pressure in confined systems generally increases by a factor of 6 – 10 (depending on the situation); in unconfined systems, the increase in volume can bring about a pressure wave with a peak overpressure of up to 100 kPa, with a positive pressure phase lasting for a few to a few hundred milliseconds (depending on the quantity of material that takes part in the spontaneous reaction, how well the fuel gas is mixed with air, how much turbulence there is to accelerate the combustion process, and how well the reacting mixture is confined). This type of explosion can be prevented "classical" anti-explosion measures (see Section 3.4.2).

The third type of chemical explosion, less well known, at least among the general public, is the "thermal runaway" explosion, initiated by a homogeneous exothermic reaction that goes out of control.

If the heat of an exothermic reaction cannot be removed, it further raises the temperature of the system. The reaction velocity increases, more heat is produced per unit time, and the system continues to heat up more and more rapidly until the maximum possible reaction velocity has been reached. The accompanying temperature rise can lead to a dangerous pressure buildup in two ways: by raising the vapor pressure of reactants and solvents, or by initiating another reaction (e.g., a decomposition) that liberates gases (see Section 2.3). If the pressure increase leads to overstressing of the reactor, it may burst and the expansion of its contents may generate a pressure wave.

In principle, an explosion can also be brought about by a purely physical process. A sudden liberation of expansion energy is possible after gases have been compressed or when vaporization is abruptly initiated, e.g., if a hot, condensed substance is quickly mixed with another substance that vaporizes readily. So far, this phenomenon does not seem to have played a major role in chemical plant explosions, and it is not discussed here; but its possibility must be considered in relation to plant safety.

Fires. Fires in chemical plants can occur if flammable substances are released and come in contact with an ignition source. Section 2.2.1 deals with the substance properties and ambient conditions that must be present for fires to start; Section 3.4 discusses measures to control fires.

The effects of fires relate to the action of heat (energy evolved mainly as thermal radiation) and the release of pollutants (combustion gases and decomposition products).

1.2. Requirements for Safe Chemical Plants

The phenomenological discussion in Section 1.1 showed that most of the dangers in the operation of chemical plants have to do with the reactivities of the substances present. The principal hazards are caused by releases and spills of substances outside the plant, and by uncontrolled chemical reactions between substances. The danger is greater, the larger the quantities of substances and energy released.

Plant and process safety efforts must have as their essential goals:

1) To minimize the quantities of substances (Section 3.1)
2) To control the potential risks that remain

Objective (2) requires:

Reliably confining hazardous substances in process equipment that can withstand the anticipated stresses (due to pressure, temperature, corrosive attack, etc.).

Insuring that process parameters (e.g., pressure, temperature, concentration) do not take on values such that the substances can undergo uncontrolled reactions.

Some help is gained from the fact that substances, as a rule, react spontaneously with one another only if they have been suitably prepared (e.g., by treatment to increase their surface area); mixed and concentrated; and excited (e.g., by heat).

Experimental laboratory tests are performed, e.g., to determine the temperature and concentration conditions under which reactions can get so far out of control that they can lead to an explosion, or to establish the initiation conditions that can cause dangerous reactions.

A point of special interest is where the regions begin in which uncontrolled reactions cannot occur. The characteristic (critical) parameters found in such experiments are called safety ratings. They include such figures as the ignition temperature and the explosion limits. Safety ratings form the basis for the safety measures in chemical plants. All of Section 2 concerns how safety ratings are determined; the account is broken down by the event classes of Section 1.1.

At the planning and design stage, plant and process safety requires taking steps so that critical concentrations, temperatures, and pressures are not reached. This is achieved by appropriate process design and process control engineering (Chap. 3). Safety also entails preventing the occurrence of potential ignition sources that could cause an undesired reaction (e.g., hot surfaces or sparks generated by mechanical or electrical equipment); great care needs to be taken in the layout of machinery and process equipment (Section 3.4).

Critical process parameters and hazardous potential ignition sources must not occur in the plant as a result of process upsets or human error. These become an additional concern of plant safety, requiring a painstaking cause-and-effect analysis of all possible errors and malfunctions, and the institution of measures to prevent or neutralize situations that could lead to an unsafe condition. Such measures may be technical or organizational; the second group includes operating instructions, inspections, etc. Chapters 3 and 4 present a fuller treatment of these points.

The complete absence of all possible hazards – absolute safety – is not possible, for several reasons.

1) First, it cannot be ruled out that several safety measures will fail simultaneously, so that a potential hazard may become an actual one
2) People make errors from time to time, and they can misjudge things, assess them wrongly, even fail to notice them at all

The fact that absolute safety is impossible is important; two inferences follow from it. Knowledge has to be continually advanced, and precautions have to be taken to avert risks in case of failure (Chap. 5).

1.3. Definitions

The fact that absolute safety is not possible leads to two key questions:

1) What does plant safety mean in the first place?
2) How safe is safe enough?

These intimately related questions can be answered in two different ways. In the first approach, safety is defined in terms of risk; a plant is said to be safe if the risk created by it is acceptable.

Here "risk" means the possibility of harm, defined in terms of the probability of the harm during the lifetime of the plant (or the frequency of the harm) and its anticipated severity.

In the second approach, a plant is said to be safe if it complies with the appropriate regulations and codes. Then it is also said to be safe enough.

While the first method is based on a probabilistic concept, risk, the second employs a deterministic principle. In both cases, what is safe is clearly a matter of convention.

The German standard DIN 31 000, Part 2, defines safety as "a state of affairs in which the risk is not greater than the greatest acceptable risk due to the technical process or condition under consideration" [7].

The standard states that this risk is generally not quantifiable, since only in rare cases can it

be expressed as R, the product of a frequency F and a measure of severity S:

$$R = FS \tag{1}$$

The standard treats danger as the diametric opposite of safety, where the risk of a process is greater than the acceptable limiting risk (Fig. 1).

A useful notion in plant and process safety is the hazard potential, a measure of the greatest harm that can occur in the worst possible event in a plant or plant subdivision. It is reasonable to use this concept in assessing safety measures in a plant: the greater the hazard potential, the more and better safety measures are needed to lower the probability of occurrence of the undesired event to the point that the level of risk is at or below the acceptable risk level.

Safety measures may include intrinsic measures and conditions [8], which insure a priori that a hazard potential can become real only in the event of a relatively improbable combination of multiple independent failures.

Where product quality considerations make it necessary to design the process and process control system so as to prevent an exothermic reaction getting out of control, safety or protective measures can be built up on the basis of this intrinsic safety in order to lower the risk to the acceptable level.

1.4. Magnitude of Hazard Potentials and Risks

The risks created by chemical plants are often overestimated if their principles are not known.

1.4.1. Risk According to Previous Experience

An anticipated value for the risk posed by chemical plants to employees or uninvolved third parties can be derived in a relatively simple way by statistical analysis of historical data.

Consider the risk of death incurred by a chemical worker due to a typical chemical accident (poisoning, chemical burn, explosion). In the Federal Republic of Germany, this risk can be determined by analysis of the annual reports of the mutual accident insurance association of chemical industry, the so-called *Berufsgenossenschaft der chemischen Industrie* [2]. When the number of persons per year suffering death from poisoning, chemical burn, fire, or explosion is divided by the total number of persons employed in the chemical industry, the annual individual lethal risk averaged over the period 1983 – 1992 is ca. 7×10^{-6} a^{-1}, i.e., statistically, 7 persons in 10^6 die every year owing to an on-the-job chemical accident. This risk is a factor of 20 less than the risk of dying in a traffic accident in Germany (ca. 1.5×10^{-4} a^{-1} [9]) and is comparable to the risk of drowning (ca. 8×10^{-6} a^{-1} [9]).

Figure 1. Risk chart [7]

Figure 2 illustrates the situation. The vertical axis shows the probability of any employee dying in the next year from one of the causes cited (individual lethal risk). For comparison, values for a range of risks, [9–12], are also plotted. In terms of a statistical average, a chemical worker is much more likely to be killed in a traffic or domestic accident than in an on-the-job accident. The worker is also more likely to be a victim of violent crime than to die in an industrial chemical accident. His on-the-job risk is low compared with other risks threatening his life.

Those living nearby and others outside the chemical plant are even safer from chemical effects, because the effects of the infrequent incidents in chemical plants fall off quite rapidly with distance. It can be assumed that this risk is, at most, of the same order as the risks due to natural catastrophes [10]. In Germany, the past 50 years have seen no identifiable serious per-

sonal injuries or deaths outside a chemical plant site resulting from accidents inside. This shows that the German chemical industry, like those in many other industrialized countries, operates very safely.

Figure 2. Comparison of lethal risks to humans (per person per year) in the Federal Republic of Germany [2], [9–11]

However, it is true that a low risk may well conceal high hazard potentials, when the probability of occurrence is low. It is therefore advantageous to consider the size of hazard potential in chemical plants.

Analysis of hazard potentials is broken down by type of accident:

Spills and releases
Explosions

1.4.2. Hazard Potential from Release of a Volatile Substance

When a volatile substance posing a health hazard is released, the hazard arises because the liberated gas is taken up by air currents, and propagates in the atmosphere as it is steadily diluted. The size of the impact area, the region in which concentration levels of the substance rise above a critical value φ_{H}, is one measure of the hazard potential; ultimately, however, the hazard potential is governed by the number of persons who stay in this impact area without protection.

To assess the hazard potential, it is necessary to determine the greatest mass of gas that can be released (in accordance with the model).

Consider a vessel that contains a mass M_{L} of a substance in the liquid state under its vapor pressure p_{v} at a temperature T_{α}, above the boiling point T_{b}. The mass of vapor in the vessel is M_{v}. If the containment fails, the contents of the vessel expand to ambient pressure; the liquid continues to vaporize and cool until the remaining liquid reaches its boiling point T_{b} at atmospheric pressure.

Because this process is very fast, it approximates to an adiabatic expansion. The mass of substance vaporized plus the original mass of vapor present are released into the atmosphere; this is the quantity that determines the hazard potential. A material and energy balance, with some simplifications, gives, for the mass vaporized:

$$\Delta M_{\mathrm{v}} = M_{\mathrm{F}(\alpha)} \left[1 - \exp\left(-c_{\mathrm{L}} \Delta T / \Delta h_{\mathrm{v}}\right)\right] \tag{2}$$

where $\Delta T = T_{\alpha} - T_{\mathrm{b}}$, c_{L} is the specific heat of the liquid, and Δh_{v} is the heat of vaporization.

If the temperature change is small, i.e., $(c_{\mathrm{L}}/\Delta h_{\mathrm{v}})\Delta T \ll 1$, a series expansion leads to the approximation:

$$\Delta M_{\mathrm{v}} \approx M_{\mathrm{F}(\alpha)} \left(c_{\mathrm{L}} \Delta T / \Delta h_{\mathrm{v}}\right) \tag{3}$$

A typical value for $c_{\mathrm{L}}/\Delta h_{\mathrm{v}}$ is $5 \times 10^{-3}\,\mathrm{K}^{-1}$. For ΔT, a value of ca. 50 °C, corresponding to an overpressure of 0.5 – 1.0 MPa, is not unusual for the storage of liquefied gases. Calculation shows that with these assumptions 20 – 30 % of the liquid contents of the vessel vaporizes spontaneously. A small additional amount vaporizes because of heat supplied from the surroundings, especially if liquid escapes from the vessel in finely divided form entrained with the vapor. In any case, this simple analysis shows that only a fraction of liquefied mass under its vapor pressure in a vessel can generally be spontaneously released into the atmosphere on failure of confinement, even when substances are kept under high pressure well above their boiling point. Only if the contents are superheated by some hundreds of degrees will the released fraction approach 100 %.

To evaluate the acute hazard created by such a process, atmospheric propagation and dilution of the gas cloud have to be calculated, but these processes show an extremely strong dependence on the motion and turbulence of the atmosphere. Results can differ by orders of magnitude; what

is more, initial dilution (e.g., dilution due to momentum of released vapor), height of release, and gas density all play roles. Exact prediction is impossible, but a rough estimate is possible [13]: under unfavorable conditions, ca. 1000 m^3 (reduced to standard temperature and pressure) or several tonnes of gas have to be released to establish maximum concentrations of ca. 10 ppm out to a range of several kilometers from the point of release. Under propagation conditions of higher probability, the concentrations drop below such levels at a range of less than 1 km [13], [19].

As a rule of thumb, a hazard to humans due to a volatile toxic gas release at a range of more than a few hundred meters from the source presupposes catastrophic failure of a vessel, and the vessel must contain several tonnes of the gas in releasable form (compressed or liquefied). Such apparatus can be found in chemical plants, but the kind of catastrophic damage under discussion is extremely improbable because such vessels are designed with safety factors against stress, and, they are subject to regular inspection.

From the safety standpoint, it is still important to assess hazard potentials relative to one another and to know how they can be influenced by process parameters.

The following argument can be of help. The simple equations describing gas propagation show [13] that the maximum concentration in a gas cloud (plume) at distance x downwind of the source is directly proportional to the quantity released M_{rel} and inversely proportional to the nth power of x:

$$\varphi = \text{const}\ (M_{\mathrm{rel}}/x^n) \tag{4}$$

where $2 < n < 3$ in general.

In the case of a release near the surface, the downwind impact area, the region swept over by a concentration higher than φ_{H}, is commonly cigar-shaped. It becomes broader and shorter, the more turbulent the atmosphere.

For a given state of atmospheric turbulence (i.e., fixed n and constant of proportionality), the (maximum) width of the impact region is always proportional to its length. Therefore, the impact region, as a measure of the hazard potential (HP), is proportional to the square of the distance x from the source to the point where the concentration falls below φ_{H}:

$$HP \sim x^2 = \text{const}\ (M_{\mathrm{rel}}/\varphi_{\mathrm{H}})^{2/n} \tag{5}$$

For the case under discussion (spontaneous vaporization and escape of a substance posing a health hazard and having a critical concentration level φ_{H}) the hazard potential is:

$$\mathrm{HP} = K \left\{ \frac{c_{\mathrm{L}} \Delta T}{\Delta h_{\mathrm{v}}} \frac{M_{\mathrm{F}(\alpha)}}{\varphi_{\mathrm{H}}} \right\}^{2/n} \tag{6}$$

Nevertheless, this is not a well-defined quantity, because K and n depend on the ambient conditions (state of motion of the atmosphere) and can only be derived from the known gas dispersion formula if a special case is assumed [13], [19].

The hazard potential is also a function of the quantity of substance, its properties, and its thermodynamic state inside the vessel. The hazard potential increases with the mass of substance present and its superheating (above boiling point), i.e., with pressure.

From this, it is possible to devise ways to reduce the hazard potential, even to the point of inherent safety.

1.4.3. Hazard Potential from an Explosion

The hazard potential of an explosion is due to the pressure wave, and is determined by the size of the (ideally circular) area around the explosion center in which there is significant damage, e.g., collapsing walls or broken windows. Window glass typically breaks at a peak overpressure in the 1 kPa range and masonry walls begin to fail at overpressures ≥ 30 kPa [14], [15]. Brasie and Simpson speak of serious damage at peak overpressures > 15 kPa [15].

The task of evaluating the hazard potential can thus be reduced to determining at what distance from the explosion center the peak pressure just falls below a critical value.

Suppose the mass M of substance being handled is such that its sudden decomposition liberates an enthalpy of reaction Δh_{r}. The total energy evolved is:

$$E = M \Delta h_{\mathrm{r}} \tag{7}$$

Hopkinson and Cranz independently found that for two distinct "charges" (releasing energies E_1 and E_2) to produce equal effects, the radii (distances R_1 and R_2 from the source point)

must be related as the cube roots of the energies [16]:

$$\frac{R_1}{R_2} = \frac{E_1^{1/3}}{E_2^{1/3}} \tag{8}$$

This result led SACHS to postulate that the dimensionless peak overpressure and the dimensionless momentum of a pressure wave (the quantities that govern the destructive action of the wave) can each be represented as a unique function of a dimensionless distance from the origin [16], [17]. The dimensionless peak overpressure $p*$ is obtained by dividing by the ambient pressure; the dimensionless range $R*$, from an expression involving the energy and ambient pressure:

$$p^* = \frac{p_\mathrm{p} - p_0}{p_0} \tag{9}$$

$$R^* = \frac{R_\mathrm{p}}{(E/p_0)^{1/3}} \tag{10}$$

The dimensional formula corresponding to Equation (10) is:

$$\frac{\mathrm{m}}{\left[\left(\frac{\mathrm{Nm \cdot m^2}}{\mathrm{N}}\right)^{1/3}\right]} = \frac{\mathrm{m}}{\mathrm{m}}$$

A diagram presented by BAKER and co-workers (Fig. 3) shows that these parameters make possible a relatively accurate dimensionless representation of the characteristic pressure-wave parameters, at least for many explosives [16].

For a provisional estimate, consider 1 t of a typical explosive, TNT (Δh_r = 4230 kJ/kg). The energy liberated in an explosion is:

$$E = (4230\mathrm{kJ/kg}) \times 1000\mathrm{kg} = 4.23 \times 10^6\,\mathrm{kJ}$$
$$= 4.23 \times 10^9\,\mathrm{Nm}$$

If p_0 = 100 kPa, Equation (10) yields:

$$R_\mathrm{p} = \left(\frac{E}{p_0}\right)^{1/3} R^* = \left(\frac{4.23 \times 10^9\,\mathrm{Nm}}{10^5\,\mathrm{N/m^2}}\right)^{1/3} R^*$$
$$R_\mathrm{p} = \left(42300\mathrm{m}^3\right)^{1/3} R^*$$
$$R_\mathrm{p} = (35\mathrm{m})\, R^* \tag{11}$$

Figure 3 yields the following dimensionless ranges:

Δp, kPa	$R*$
30	ca. 1.5
15	ca. 2
1	ca. 20

Thus, Equation (11) implies that an explosion corresponding to the detonation of 1 t of TNT would break windowpanes (Δp=1 kPa) out to a range of several hundred meters (R_p = (35 m)×$R*$ = 700 m) and cause serious damage (Δp = 15 kPa) in a circle radius 50 – 100 m (R_p = 70 m).

Figure 3. Dimensionless peak overpressure in an explosion pressure wave as a function of dimensionless distance from the source [16]
The expression for the dimensionless distance involves the explosion energy and the initial pressure

Explosives and similar materials are not commonly used in chemical plants. Reactions that can lead to explosion-like phenomena (Sections 1.1.2) are governed by other laws and differ strongly in kinetics, enthalpies of reaction, and efficiencies (in terms of energy conversion). For this reason, no direct comparison with the explosion just described is possible.

Even so, a number of workers have sought correlations [4], [18]. MARSHALL [1.3, p. 256], working with event analyses for explosions of unconfined gas clouds, arrives at the conclusion that for less than ca. 1 t of fuel gas forming an unconfined explosive cloud, peak overpressures

on ignition are negligibly low. He estimates that for an unconfined cloud with $> 10\,t$ fuel gas, about 5 % of the liberated energy (of combustion) can contribute to a TNT-equivalent pressure wave, but with significantly lower pressures ($< 100\,kPa$) in the near region.

Hence, 2 t fuel gas reacting to completion would produce the same effect as 1 t TNT (with allowance for the fact that the enthalpy of combustion of a fuel gas is a factor of 10 greater than the energy of TNT decomposition).

In a real unconfined gas cloud formed through damage to a vessel or in a plant, only a fraction of the fuel gas is ever in a region where the concentration is high enough for sudden combustion – in the worst case. It must therefore be supposed that the effect produced by the explosion of 1 t TNT can be matched only by the spontaneous release and ignition of ca. 10 t fuel gas. This could not happen without serious damage to a large vessel.

The hazard potential of an explosion is directly proportional to the area within which a certain level of damage occurs. According to Equations (8) or (10) and (7):

$$HP \sim R^2 \sim E^{2/3} = (M\,\Delta h_r)^{2/3} \tag{13}$$

i.e., the hazard potential increase is less than directly proportional to the energy release and the mass involved.

1.5. Conclusions

The analyses given here show, as does experience, that chemical plants may occasionally represent high hazard potentials, especially when volatile substances of a flammable or health-endangering nature are processed in large quantities, and when exothermic (decomposition and combustion) reactions are possible.

It is also clear that, while hazards can be identified and analyzed, the magnitude of hazard potentials cannot be quantified precisely. For the design of safe processes and plants, a qualitative order-of-magnitude estimate, a relative comparison with other hazard potentials, and an identification of key independent variables is sufficient, because such considerations give a point of reference such that hazard potentials can be reduced in the most efficient way, and safety measures and equipment can be designed to handle the remaining potentials (Chap. 3).

Experience has led to the low risk values cited for chemical plants and shown that major chemical plant accidents have been infrequent, especially in view of the scope of industrial activity in this field. The advanced chemical industry has obviously had much success in controlling its hazard potentials.

2. Determination and Evaluation of Hazardous Properties of Substances (Safety Ratings)

2.1. Harmful Effects of Substances

According to the EC classification criteria [20], substances are described in terms of 15 hazard-related characteristics, which can be broken down into four groups:

1) *Acute Toxicity:*
   Very toxic substances
   Toxic substances
   Harmful substances
   Corrosive substances
   Irritant substances
2) *Specific Toxic Properties:*
   Sensitizing substances
   Carcinogens
   Substances with effects on reproduction
   Substances with heritable effects
3) *Physicochemical Properties:*
   Extremely flammable substances
   Highly flammable substances
   Flammable substances
   Oxidizing substances
   Explosive substances
4) *Environmental Impacts:*
   Substances harmful to the environment

While acute and specific toxic properties can cause direct harm to health, physicochemical properties lead to indirect harm. Substances can take any of three routes into the body:

Oral: by mouth directly into the stomach
Dermal: through the skin
Inhalation: via the respiratory organs

The actions of a substance can differ greatly depending on the route of exposure. Because of the acidic conditions in some regions of the gastrointestinal tract (pH 1 – 5), hydrolyzable substances can be broken down after oral intake. Chemical reactions can lead to both more toxic substances (metabolic activation) and less toxic ones (detoxification). While acidic compounds are preferentially absorbed in the stomach, basic and lipophilic substances are preferentially taken up in the intestinal tract. Chemicals not resorbed in either the stomach or the intestines can be excreted directly without realizing their toxic potential (e.g., mercury, barium sulfate).

The skin protects the body against external effects. It performs very effectively against substances readily soluble in water. Fat-soluble (lipophilic) substances, on the other hand, commonly diffuse well through the skin into the body. Dermal resorption is extremely effective for polar molecules with lipophilic and hydrophilic groups (e.g., many organic solvents such as dimethyl formamide, dimethyl sulfoxide, ethyl acetate, toluene, chloroform). Corrosive chemicals resorbed through the skin (e.g., phenol) are taken up very quickly and effectively by this route.

Highly corrosive substances are those that destroy the skin (necrosis) if allowed to act for a maximum of 3 min; corrosive substances have the same effect within 4 h. Examples of highly corrosive substances are inorganic acids and alkalies. In general, the corrosive action of alkaline substances is stronger than that of acids.

Irritant substances are characterized by inflammation of the skin after a maximum of 4 h exposure (e.g., dilute acids and alkalies, weak organic acids, acrylates, alcohols, amines). While the irritant action of substances is reversible, corrosive action implies irreversible injury. The mucosa of the eyes and respiratory passages are particularly sensitive to irritation.

Highly water-soluble substances, when taken up by inhalation, are generally absorbed by the mucosa in the upper part of the trachea, and do not reach the deeper layers of the lung. Because many receptors are present, irritation reactions such as coughing and sneezing may be initiated by agents such as ammonia, hydrogen chloride, sulfur dioxide, and vapors of acids and alkalies.

Compounds that are less water-soluble can readily penetrate into the bronchi. Partial diffusion through the thin bronchial tissue is possible and can lead to lung injury (e.g., chlorine, bromine, iodine, ozone, phosphorus chlorides).

If the tissue of the lung suffers local corrosion, liquid can seep into the alveoli (pulmonary edema) and the oxygen transfer required for life can be hindered for hours to days after exposure (latent action; e.g., phosgene, nitrogen dioxide, ozone, some isocyanates). Lipophilic compounds, in particular, can cross over via the alveoli when respired air is exchanged with the blood.

Substances with systemic action, after inhalation or oral or dermal exposure, are distributed throughout the body by the circulatory system. In this way they can reach all organs.

If injury takes place only at the point of exposure, the substance is said to have a local action.

With regard to acute toxic effects, substances are classed as very toxic, toxic, or harmful. This description is based on the median lethal dose LD_{50}: the dose at which half of the experimental animals die. Toxicity is reported as oral, dermal, or by inhalation. Oral and dermal LD_{50} values are given in milligrams of the substance per kilogram of the experimental animal for one-time administration; LD_{50} values by inhalation are given in milligrams of the substance per liter of respired air (exposure time 4 h). Because oral toxicity values are more common, they alone are discussed here.

The lethal dose represents only the end point of toxic effects. The toxic action, however, begins to appear even when much smaller quantities are present in the body. The dose at which no biologically relevant effect can be detected is called the no adverse effect level (NOAEL).

Table 1 shows how substances are classified in accordance with EU guidelines [20]. Substances are arranged by acute toxicity properties; the table also gives danger symbols and indications along with the "R phrases" (which specify the principal risk more closely). In some non-European countries, the boundaries between classes differ slightly from the values shown.

Table 1. LD_{50} values (oral)

Attribute	LD_{50}, mg/kg	Symbol	R phrases
Very toxic	<25	T+	26, 27, 28
Toxic	25 – 200	T	23, 24, 25
Harmful	200 – 2000	Xn	20, 21, 22

Substances with LD_{50} (oral) values over 2 g/kg do not, according to past experience, require special precautions; these are no longer classed as hazardous substances.

Sensitizing substances are those that evoke an allergic reaction in a large number of individuals, either on the skin (skin or contact allergy; e.g., formaldehyde, glutaraldehyde, alkyl acrylate) or in the respiratory passages (respiratory allergy; e.g., phthalic anhydride, isocyanates). Sensitizing reactions of chemicals cannot be distinguished from allergic reactions to agents such as flour, pollen, and animal hair.

Substances that threaten the ability to reproduce are termed reproductive toxins or substances with effects on reproduction. Such effects are classified as:

Developmental Injuries (symbol R_E). These effects include birth defects (teratogenic effects) and embryo- or fetotoxic effects such as low weight and growth or developmental disorders of the unborn child.

Impaired Fertility (symbol R_F). The EU classification criteria [20] divide substances with effects on reproduction into three categories:

Category 1. Substances known to have effects on reproduction in humans.

Category 2. Substances that should be regarded as having effects on reproduction on the basis of animal studies.

Category 3. Substances suspected of having effects on reproduction.

The labeling requirements in countries of the European Union are summarized in Table 2 [20].

Table 2. Classification of reproductively toxic substances according to the EU guidelines [20]

	Category 1	Category 2	Category 3
Hazard symbol	T	T	Xn
Classification	toxic	toxic	harmful
R phrase	60 (R_F), 61 (R_E)	60 (R_F), 61 (R_E)	62 (R_F), 63 (R_E)

Some countries have regulations different from the EU scheme. For example, the MAK Commission in Germany classifies substances with respect to the MAK value (*maximale Arbeitsplatzkonzentration* = maximum occupational exposure concentration) [21]:

Pregnancy group A. A risk of fetal injury has been demonstrated. Injury cannot be ruled out, even if the MAK value is complied with.

Pregnancy group B. A risk of fetal injury cannot be ruled out, even if the MAK value is complied with.

Pregnancy group C. A risk of fetal injury need not be feared if the MAK value is complied with.

If a health hazard is posed, not by one-time exposure to the substance, but by quantities administered over a longer period, the terms subacute, subchronic, and chronic are employed, depending on the exposure time. Carcinogenicity is merely one specific chronic effect.

Carcinogenic substances can initiate tumors. A tumor is an uncontrolled cell growth that penetrates surrounding cells in infiltrative fashion and destroys them. The latency period (time between exposure and externally detectable cancer growth) is typically 20 – 40 a for chemical carcinogens. According to the EU criteria, carcinogenic substances are classified as follows [20]:

Category 1. Known to be carcinogenic in humans.

Category 2. Unambiguously carcinogenic in animal trials.

Category 3. Suspected of being carcinogenic.

Labeling requirements under the EU scheme [20] are listed in Table 3.

Table 3. Classification of carcinogenic substances according to the EU guidelines [20]

	Category 1	Category 2	Category 3
Hazard symbol	T	T	Xn
Classification	toxic	toxic	harmful
R phrase	45 (gases, vapors) 49 (dusts)	45 (gases, vapors) 49 (dusts)	40

The best-known substances in Category 1 are asbestos, benzene, benzidine, β-naphtylamine, and vinyl chloride; in Category 2, acrylonitrile, butadiene, and *N*-nitrosamines.

The classification of the German MAK Commission [21], [261] is very similar to the EU scheme (Table 4).

Table 4. Comparison of classifications of carcinogenic substances

	MAK Commission	EU Classification
Letter codes	K	C
Human carcinogens	1	Category 1
Animal carcinogens	2	Category 2
Suspected carcinogens (classification is temporary)	B	Category 3
Carcinogens without genetoxic effect	4	–
Carcinogens with genetoxic effect	5	–

MAK = maximum workplace concentration (Germany), *GefStoffV* = hazardous materials regulation

From the standpoint of toxicological action, substances causing heritable genetic damage do not differ fundamentally from carcinogens; the injury they cause, however, is to the genetic information of the germ cells rather than to that of the body cells. The classification again includes Categories 1 – 3. No Category 1 chemicals causing heritable genetic damage are known.

The classification of hazardous substances on the basis of thermal properties employs the flash point (Table 5). Substances are characterized as oxidizing if they can sustain combustion with the exclusion of oxygen. The symbol O is used in their labeling (e.g., permanganates, bromates, hypochlorites, chlorites, nitrates).

Table 5. Thermal properties according to EC guidelines [20]

Property	Flashpoint, °C
Extremely flammable∗	< 0
Highly flammable	< 21
Flammable	21

∗ *bp* must be < 35 °C.

Substances with a greater explosive tendency than dinitrobenzene (reference substance) are described as explosive, and must be labeled with the symbol E (e.g., picrates, pentaerythritol tetranitrate, many organic peroxides).

In order to assess the workplace, the concentration of hazardous substances must be determined and compared with the applicable workplace concentration limits (see § 18 of the *German Hazardous Materials Regulation* [22]). The most important limits for workplace air are the German MAKs [21] and the American TLVs (threshold limit values) [23]. If these limits are maintained, no damage to health is to be feared, given a daily exposure time of 8 h and a weekly exposure time of 40 h for healthy adult workers over a working lifetime (50 a). The OEL values (occupational exposure levels) set by the EU Commission [24] are also determined primarily on scientific grounds. Because no health hazard is present if these limits are satisfied, they are less than the NOAELs mentioned earlier. The limits cited are defined as the maximum permissible concentrations averaged over one working day (shift averages). For this reason, exposure peaks must be limited. Substances are classified in exposure peak groups according to their toxicological action profiles. According to, say, the provisions of the German MAK Commission, maximum exposure levels are 2 – 10 times the MAK. Substance-specific STELs (short-term exposure levels) are also established in the United States. For a few substances, "ceiling values" are also stated; it is prohibited to exceed these at any time [23].

Because NOAELs cannot be established for carcinogens and substances with heritable effects, some countries have not established medically and toxicologically justified limits for them. In Germany, for example, TRK values (*Technische Richtkonzentration* = technical guideline concentration) can be set for carcinogens, instead of MAKs [25]. A TRK represents the exposure level that can be reached at the state of the art. If the TRK is observed, acute health hazards are eliminated; the cancer risk is minimized, but not completely eliminated. These TRKs are also 8h or shift averages.

For important industrial chemicals not governed by limits, the chemical industry has created internal guidelines on its own initiative. The results are called PELs (permissible exposure limits) in the United States and ARWs (*Arbeitsplatzrichtwerte* = workplace guideline values) in Germany [26]. All workplace exposure levels are now summarized in Germany in a single guideline [27].

With regard to protective practices, technical measures always take priority over personal protective measures (see, e.g., § 19 of the *GefStoffV* [22]). Only when the use of enclosed apparatus is not reasonable can other measures consistent with the protective objective be used, e.g., the application of suction at the source in sampling, filling, and draining operations. The use of respiratory protection is permitted only temporarily,

for short-term activities, and employment as a long-term measure is not permitted.

In order to prevent dermal intoxication, suitable body protection must always be worn when working with chemicals. Polar compounds, in particular, commonly diffuse very rapidly through ordinary glove materials; breakdown times reported by manufacturers must always be observed. For further details, see [28].

In the preparation of the safety analysis pursuant to the *Störfallverordnung* (The Seveso Directive of the EU), the hazards due to product release in an emergency must be determined. With the aid of generally accepted propagation calculations (e.g., VDI 3783), the concentration in the region near a plant is calculated on the basis of a plausible leakage rate. "Accident rating values" are employed in assessing the health risk. These limits, worked out by the German chemical industry, represent concentrations such that there is no immediate danger to life, given a maximum exposure time of 0.5 h. Temporary impairment of health cannot, however, be completely ruled out.

2.2. Ratings of Flammable and Explosive Substances

2.2.1. Flammability Ratings

2.2.1.1. Introduction

A variety of data and experimental techniques can be used to characterize flammability and combustibility. Requirements as to fire behavior and fire resistance apply not just to chemicals themselves, but also to the materials and structures used in buildings where chemicals are handled.

2.2.1.2. Combustibility/Flammability of Chemicals

Combustion is a reaction that takes place in the gas phase and involves oxygen or another oxidizing agent present in the ambient gas phase. The flame phenomenon is characteristic of the reaction for liquids, gases, and most solids; constituents previously vaporized or carbonized and mixed with oxygen by diffusion oxidize in the flame. Any residue in, e.g., coke-like form, is heated to incandescence in this process and then reacts with oxygen present at the surface of the solid and diffusing into its pores. Substances such as pure carbon or iron, which do not vaporize sufficiently at the temperatures under consideration, react by glowing [29].

The speed of a self-sustaining combustion process depends on the rate of reaction, the heat liberated in the reaction, and the balance of reaction heat, heat loss to the surroundings, and heat required for melting/vaporization.

Combustibility of Liquids. The safety parameters flash point and ignition point are used to characterize the flammability of liquids.

The flash point is the temperature of a liquid, tested in a certain apparatus and under certain conditions, at which the gas phase above the liquid can burst into flame when an ignition source is brought near. The flash point is measured in various test methods [30], [31], e.g., DIN 51 755, DIN 51 758, and DIN 53 213 for Germany; GOST 12.1.044-84 for the Russian Federation; BS 2000 Part 34 and Part 170 for the United Kingdom; and ASTM D 56-87, ASTM D 3278-89, and ASTM D 93-90 for the United States. All test setups and specifications allow for the fact that the flash point is a rough measure because of the tolerated uncertainty of measurement and the variation of material properties (e.g., viscosity).

The two basic types of apparatus are the open and closed cups. Methods differ in the access of oxygen and in the quality of mixing or accumulation of fuel over the liquid. Methods can also be classified as thermodynamic equilibrium or nonequilibrium, and a given test substance may show different flash points in these two kinds of test.

In spite of national and international differences, all the methods yield data sufficiently reliable for safety assessments.

Figure 4 shows one setup for flash point determination.

If the temperature of a liquid exceeds the flash point, flammable mixtures with air may form over the liquid. As a rule, combustion of this mixture does not result in self-sustaining combustion of the liquid; this is possible only when its temperature is raised (by a few degrees celsius) to the combustion point. Even then, it

is necessary that the temperature rise does not cause any further inert constituents (e.g., water in spirits of very low alcohol content) to go into the gas phase.

Figure 4. Flash point test equipment
Examples of flash point values (°C): Diethyl ether, gasoline − 20; ethanol 12; rum (40 vol %) − 27; diesel fuel 55; glycerine 160

Internationally, the flash point is the basis for placing substances in hazard classes with regard to ignitability. Under international transportation law [30], a liquid is classed as flammable if it has a flash point $< 60.5\,°C$ (closed cup) or 65.6 °C (open cup) or if it is handled at a temperature higher than the flash point. Self-sustaining combustion is tested in a separate procedure [32]. If a substance with flash point $> 35\,°C$ does not continue to burn after ignition in this test, it is not placed in Class 3 (flammable liquids); this rule takes into account the reduced risk of fire.

According to the German regulations (e.g., the VbF (Verordnung brennbarer Flüssigkeiten) or Flammable Liquids Regulation [31]), a substance having flash point $\leq 100\,°C$ is classified as combustible. Liquids miscible (extinguishable) with water make up Hazard Class B; those not miscible with water, Hazard Class A. Details of the classification are as follows:

Hazard Class A
Liquids with flash point $\leq 100\,°C$ which do not have the water solubility characteristics of Hazard Class B

A I: flash point $< 21\,°C$
A II: flash point 21 – 55 °C
A III: flash point 55 – 100 °C

Hazard Class B
Liquids with flash point $< 21\,°C$ which are soluble in water at 15 °C or whose combustible components are soluble in water at 15 °C

Type of reaction	Class	Reference product
No spreading of fire		
no ignition	BZ 1	table salt
brief ignition and rapid extinction	BZ 2	tartaric acid
localized combustion or glowing with practically no spreading	BZ 3	D-lactose
Fire spreads		
glowing without sparks (smoldering) or slow decomposition without flame	BZ 4	protonic acids; tobacco
burning with flame or spark generation	BZ 5	sulfur
very rapid combustion with flame propagation or rapid decomposition without flame	BZ 6	black powder

Figure 5. Flammability index test equipment

Combustibility of Solids (Dusts). The combustibility/flammability of solids is characterized by the flammability index [33] and the burning rate [33], [34] of an uncompacted layer of dust. The flammability index gives a qualitative description of how such a bed of dust behaves when a strong ignition source (igniting flame, incandescent coil) is applied to it (Fig. 5). A substance with flammability index > 3 tends to keep burning after local ignition; a burning-rate test must be performed on such a substance. For flammability index ≤ 3, the substance generally shows no tendency to rapid flame propagation. On the basis of a burning-rate test (flame path 100 mm, time limit 45 s),

solids are classified as highly flammable or not highly flammable, but these terms are misleading because they both relate to the rate at which a fire spreads once started, not the tendency of a substance to catch fire.

Beside ignition from an outside source, another concern with dusts is the spontaneous flammability in air or other gaseous oxidizing medium due to self-heating. VDI 2263 describes the Grewer accelerated test (Fig. 6) and the heat-aging tests used to characterize the spontaneous flammability of dusts. Volumes of the dust ranging from 5 to 1000 mL are subjected to a programmed variation in temperature in the presence of (usually flowing) oxidant, and the behavior of the dust sample is recorded. Maximum permissible storage and surface temperatures can be derived from the results with the aid of mathematical models and appropriate safety margins. Similar test methods, with other volumes of dust tested in other containers (square, cylindrical), are used in Transportation Class 4.2 testing under international transportation law [30], and in spontaneous flammability testing pursuant to the *Chemikaliengesetz* (Chemicals Act) [34].

Figure 6. Grewer test apparatus for testing spontaneous flammability of dusts (VDE 2263)
a) Temperature recording; b) Thermocouples; c) Test substance (8-cm^3 wire basket); d) Reference substance; e) Packing; f) Temperature-controlled housing

Applicability of Flammability Data. The combustibility measures described up to this point are based on standard test methods. The data cannot be extended to practical conditions unless possible variations in the ambient conditions are taken into account. The flash point, for example, depends heavily on pressure as well as oxidizing medium. Changes in these lead to changes in fire behavior. The temperature of spontaneous ignition can also fall markedly below the ignition temperature of DIN 51 794 if organic liquids (including heat-transfer media) penetrate into open-pored insulants such as rock wool.

Assessment of dusts is likewise based on the experimental conditions (air as oxidizing medium, adequate heat removal from combustion zone). If the partial pressure of oxygen is increased, a stronger oxidizing agent is employed, the heat-removal conditions are made worse (storage in large drums, silos, etc.), or the ambient temperature is higher, an increased risk of fire must be expected.

In the case of solids or ointments containing solvents, it has to be decided case by case whether the flash point or the burning rate/flammability index better describes the situation.

2.2.1.3. Oxidizing Properties of Chemicals

Oxidizing substances in contact with combustible substances, give off oxygen or other oxidizing agents so as to increase the danger of fire or the vigor with which the combustibles burn. As a rule, oxidizing substances are not themselves combustible. In the pan-European market area, testing is done pursuant to Directive 84/449/EEC Annex A 17 [34]. Various mixtures of the test substance with cellulose powder are prepared and the burning rates are determined; the results are compared with the burning rate of a reference mixture of barium nitrate and cellulose. A substance is classified as oxidizing if the burning rate of a test mixture is greater than that of the reference mixture. As a rule, incorrect predictions are made if this test procedure is applied to liquids or to melting and highly flammable (combustible) substances, so its use with these substances is ruled out. A comparable test method is employed internationally for the

transportation of hazardous substances [30]. In some instances, the two procedures give different classifications for the same substance.

Oxidizing properties make a chemical a hazardous substance, and safety regulations apply to its storage and transportation.

Table 6. Classification and test method for building materials [35]

Building material class	Building inspection designation	Test method
Class A	noncombustible	
A 1 ∗		furnace test 750 °C
A 2		Brandschacht
		smoke density to ASTM D 2843-70 and DIN E 53 436/37
		toxicity to DIN 53436
		calorific potential to DIN 51 900 Part 2 and heat release to DIN 4102
		Part 8 or furnace test 750 °C
Class B	combustible	
B 1 ∗∗	low flammability	Brandschacht and small burner test
		special case of floor coverings, radiant panel test (NBSIR 75-950) including evaluation of smoke density
B 2	moderately flammable	small burner test
		special case of textile floor coverings (DIN 54 332)
B 3	highly flammable	no tests, no compliance with *B 2*

∗ *Class A 2* requirements must also be satisfied.
∗∗ *Class A 2* requirements must also be satisfied.

2.2.1.4. Flammability of Construction Materials

For fire precautions to be effective, they must take into account not only the combustibility of chemicals, but also the fire behavior of construction materials and structures, floor coverings, and other items within the production facility.

In Germany, structures and construction materials are tested as set forth in DIN 4102 [35]. Evaluated along with the fire endurance are the flammability, the burning rate, the toxicity of the combustion gases, and (for structures) the mechanical strength. The fire endurance is stated in minutes, for example F 30, F 60, F 90. DIN 4102 requires a fire endurance of F 90 for firewalls. Construction materials are classified as combustible or noncombustible according to the test results (Table 6).

Outside the Federal Republic of Germany, standards for assessing the combustibility of construction materials and other substances vary from country to country. A comprehensive survey of national regulations can be found in [35].

2.2.2. Explosion Data for Gas Mixtures

(General References: [36–40])

2.2.2.1. Introduction

In any operation on combustible and/or unstable gases, explosive systems may be formed and explosions initiated. This danger can be effectively countered only if the safety characteristics of the gases involved are well known. These characteristics are not constants in the physical sense, for they are influenced by the method used to determine them. There is no generally accepted method for estimating and calculating them, although for a few characteristics empirical formulas exist for specific groups of substances [41]. In other words, recourse must be had to the experimental methods described in the following sections. Laboratory values must be of such a quality that they can serve as a basis for explosion-protection measures in full-scale plants. This is possible only if the method of determination is standardized or meets other requirements derived from experience. The link between parameters and explosion-protection measures must be taken into account, even in bench-scale determination; this link essentially has to do with the type of plant and the process parameters, regardless of whether explosion protection is achieved through precautions or constructional measures.

2.2.2.2. Explosion Limits; Limiting Oxygen Concentration

A gas explosion is a rapid chemical reaction (oxidation) in the gas phase, which propagates through the explosive mixture in a self-sustaining process. Because the reaction proceeds rapidly, the heat released leads rapidly to high temperatures, and can result in the buildup of high pressures, especially in enclosed vessels.

A gas explosion requires the presence of an explosive mixture consisting of a finely dispersed fuel in an oxidizer (oxidizing medium) and the simultaneous presence of an effective ignition source. Fuels include all combustible gases (e.g., hydrogen, methane, carbon monoxide, ethylene) as well as combustible vapors such as those of the volatile hydrocarbons. The oxidizer is commonly atmospheric oxygen, but there are other oxidizing gases, the most important being chlorine, fluorine, ozone, nitrous oxide, nitric oxide, and nitrogen dioxide. Inert gases such as nitrogen and carbon dioxide play an indirect role in explosion reactions.

Any gaseous system containing mixed fuel and oxidizer is explosive only within a certain concentration range, the "explosion range", governed by the properties of the substances involved and by pressure and temperature. In practice, there is often only one fuel and air is the oxidizer; here the explosion range can be characterized simply by stating the concentration limits of the fuel in air. These bounds, the lower explosion limit (LEL) and the upper explosion limit (UEL) have been tabulated for a number of combustible gases and vapors [42], [43].

Nonexplosive mixtures in the range below the LEL are said to be "too lean" and those above the UEL are said to be "too rich."

The explosion limit itself is defined quite generally as the fuel concentration such that an explosive reaction initiated by an outside source just fails to propagate through the mixture in a self-sustained fashion. In practice, the explosion limit is recognized by the fact that the visible flame (present in virtually all gas explosions and directly tied to the reaction zone) just fails to detach from the ignition source; in other words, the velocity of flame propagation becomes zero. This flame propagation velocity or combustion rate can take values from a few centimeters per second up to several kilometers per second in the case of detonations. It is not an important parameter, except in certain technical systems with precisely defined boundary conditions (e.g., the internal combustion engine).

One basic explosion-protection measure is to prevent the formation of explosive mixtures, i.e., to keep the mixture composition outside the explosion range (see also Section 3.4.2). This requires an accurate knowledge of the explosion limits for the system.

Any apparatus for determining explosion limits must satisfy definite minimum requirements, since the limits relate not just to thermal conditions, but also to reaction kinetics.

A set-up for measuring the explosion limits of gases should therefore comprise a heated cylindrical glass vessel (ca. 1 L) with inner diameter ≥ 6 cm, set with its axis vertical, and an ignition source located on-axis in the bottom third (Fig. 7). The boundary of the ignition vessel is thus sufficiently far from the ignition point and has only a slight deactivating (explosion-hindering) action; the propagation or detachment of the flame can be observed visually and is not hindered by the burned gases, which are free to escape upward.

Figure 7. Apparatus for determining the explosion limits of gases
a) Ignition vessel; b) Ignition electrodes; c) Mixture preparation; d) Three-way valve

The criterion for a self-sustaining progressive combustion reaction (explosion) is the visually observed detachment of a flame from the ignition source (Fig. 8, [44]). Each ignition trial must be done in a stationary mixture, since movement (e.g., flow) of the unburned mixture, especially at the explosion limits, leads to additional transport of heat and free radicals out of the ignition volume, and this can interfere with the formation of the explosion reaction.

A proven way of delivering energy to initiate the reaction is with an induction spark (e.g., that generated with a 15 kV transformer) lasting ca. 0.2 – 0.5 s; the spark jumps a gap of 5 mm between two pointed rod electrodes ca. 3 mm diameter.

Figure 8. Flame detachment criterion
A) No flame detachment; B) Flame detachment

To determine the explosion limits accurately, the preparation of the mixture and its transfer into the test vessel must introduce as little error as possible. Calibrated devices must be used to meter the volume flow rates (of gases) and mass flow rates (of totally vaporized liquid mixtures). Temperature control, especially of the ignition vessel, should be as gradient-free as possible.

Gas-metering pumps with volumetric delivery have been found satisfactory for preparing pure gas mixtures. The test vessel must be adequately purged with the test gas mixture before every ignition trial, to remove burned or unburned residues and so that the vessel wall is sufficiently conditioned. To insure constant mixture composition, it is useful to avoid interrupting the flow of mixture during the trial; a three-way valve can be used to bypass the mixture around the vessel.

In pure gas mixtures, the explosion limits are generally stated in percentage by volume of fuel gas relative to the total mixture (vol %). This is appropriate when the mixture is prepared with a metering device with volumetric delivery. Otherwise, the limits should be based on the molar ratio (mol %).

If care is taken in operating the mixture preparation and explosion devices, explosion limits can be determined to an accuracy of ca. ± 0.1 vol % [44].

When the UEL is being determined, it should be kept in mind that some substances, such as acetylene and ethylene oxide, can decompose explosively without the presence of oxidizer; this can result in an observable flame detachment or pressure rise not attributable to an oxidative gas explosion, and it may not be possible to state an UEL. Because the effects of explosive decomposition (e.g., the maximum pressure) may actually surpass those of an oxidative gas explosion, a UEL of 100 vol % is reported and the decomposability of the substance is noted [42].

In the case of an explosive gas mixture containing several fuel species, if the concentrations and the explosion limits of the individual fuels are known, the explosion limit of the fuel mixture can be calculated, provided certain mixing rules (e.g., that of Le Chatelier [45]) are known to hold (see also [46]). As a rule, this gives satisfactory results only for the LEL.

If explosion limits must be determined for an elevated initial pressure, the tests must be carried out in a closed, pressure-tight apparatus, such as that used for measuring the maximum explosion pressure and the maximum rate of pressure rise (see Section 2.2.2.3).

Along with tables of LELs and UELs for combustible gases and vapors in air [42], [43], a triangular plot (explosion diagram) can also be used for systems of three or more components. The triangular plot displays the LEL, UEL, limiting oxygen concentration $[O_{2max}]$, and characteristic concentration ratios needed to avoid explosive mixtures. Figure 9 presents such a diagram for a hydrocarbon/nitrogen/oxygen system; the explosive region is shaded. Each concentration (fuel on the base of the triangle, inert gas on the right leg, oxygen on the left leg) is shown increasing in the counterclockwise direction. In systems with more components, those whose concentration ratio is held constant can be plotted on one axis; for example, air ($[N_2]/[O_2]=3.76$) can be plotted as one species if CO_2 is introduced as an additional (inert) component. The so-called air line, joining 0 vol % N_2 (point B) and 21 vol % O_2 connects all mixture compositions in which the concentration ratio $[N_2]/[O_2]$ is constant at 3.76. Points L and U where the boundary of the explosive region intersects this line give the lower and upper explosion limits in air. The tangent to the explosive region boundary parallel to the N_2-axis cuts the O_2-axis at point D, which defines an O_2 concentration below which no explosion can take place because of the deficiency of oxygen, regardless of how much fuel or N_2 is present (partial inertization). This O_2 concentration (point D) is called the limiting oxygen concentration $[O_{2max}]$; it is a key parameter in the design of inert-gas blanketing (including that for plant-scale equipment), and the oxygen level must

never be permitted to exceed it. A detailed explanation of the triangular diagram has appeared in [47]. Limiting oxygen concentrations for some substances are listed in [48].

Figure 9. Triangular plot for a hydrocarbon – oxygen – nitrogen system

In practice, inerting is often best achieved by monitoring just one component, commonly the oxygen level at partial inertization, because ratio monitoring is generally more involved and expensive.

Since the explosion reaction depends on pressure and temperature, so do the explosion limits. Generally as pressure increases and temperature rises, the explosion range becomes larger. This change is much more strongly marked near the UEL than at the LEL, as Figure 10 illustrates for ethylene. The limiting oxygen concentration decreases as the pressure increases. The explosion limits and the limiting oxygen concentration vary similarly with temperature [49]. An exception is the pressure dependence of the explosion limits of hydrogen; with increasing pressure the explosion range for hydrogen does not become wider but narrower [50]. A similar behavior was found for carbon monoxide.

In the design of explosion-protection measures, it must be kept in mind that the safety-relevant parameters employed are those that apply to the conditions (pressure, temperature) of the particular application.

At present, explosion limits can be calculated only by fitting experimental data, because simulation models do not offer an adequate (substance-specific) description of the physicochemical conditions at the explosion limit.

Figure 10. Pressure dependence of the explosion range

2.2.2.3. Maximum Explosion Pressure and Maximum Rate of Pressure Rise

In chemical process engineering, it is frequently not possible to avoid working with reactive gas systems in closed equipment. Avoiding potential ignition sources is often not sufficient to insure safe working conditions. The hazardous effects of an explosion on the equipment and its surroundings, including people, can be averted only through design measures [48]. The elimination of ignition sources is necessary, if only for economic reasons, as a supplementary measure. Before protective practices are planned, the following question must be elucidated: can the gas system become capable of detonation (occurrence of shock waves) as a result of the operating conditions (pressure, temperature, composition) or the geometry of the apparatus (long vessels, piping) ? If so, the discussion that follows does not apply. If the occurrence of detonations can be ruled out with confidence, it is possible to design vessels and piping such that they can withstand a deflagrative explosion. The principle of pressure-resistant or pressure-shock-resistant design is employed in such cases.

In pressure-resistant design, the anticipated explosion pressure must not exceed the design pressure; in shock-resistant design, the pressure is allowed to go above the design pressure, and

deformations are allowed, provided the system remains tight (deformed parts must be replaced after such an event).

For either of these design approaches, the maximum anticipated explosion pressure generated by the gas system under the design operating conditions must be known. In simple systems, a theoretical calculation is possible, but in other cases the maximum explosion pressure has to be determined experimentally.

If economics dictates that pressure-resistant or shock-resistant design not be used, pressure relief is still a design option for drastically reducing the pressure loads. The design of rupture disks and explosion doors requires knowledge of (among other parameters) the maximum rate of pressure rise in the anticipated explosion. This cannot be calculated theoretically and must be determined experimentally for every application [51–53].

When pressure relief is employed for protection – an approach calling for a high degree of experience – it must not be forgotten that the release of products into the atmosphere may infringe air pollution control regulations. Both the maximum explosion pressure $p_{\max}$ and the maximum rate of pressure rise $(\mathrm{d}p/\mathrm{d}t)_{\max}$, are measured in a single laboratory trial. There is no single prescribed method for determining these parameters. The requirement that bench-scale measurements must be suitable for the design of much larger equipment is best met by using a spherical autoclave with the ignition source at the center of the explosion vessel. This choice stems from the knowledge that the flame front of a gas explosion propagates through the mixture as a sphere, centered at the point of initiation [54]. To allow the reactions to proceed in virtually adiabatic fashion (i.e., to minimize heat loss through the autoclave wall in comparison with the total heat of reaction), the distance between the igniter and the wall must be ≥ 10 cm. Otherwise, excessive heat loss causes the measured values to be too low and yields poor estimates of the safety ratings [55]. An autoclave with a pressure rating of ca. 100 MPa at 200 °C covers the pressure and temperature ranges of practical interest in such studies. Proven types of initiators are wire igniters and surface-discharge plugs.

Energies, which depend not only on the electrical parameters, but also on the gas and the pressure, are 50 – 80 J [56].

The following instrumentation chain is recommended for recording the time dependence of pressure during reactions:

1) Pressure transducer with appropriate range; pressure-sensing membrane must make a tight seal in the autoclave wall
2) Amplifier adapted to the pressure pickup
3) Digital storage oscilloscope or computer with measuring card

For undistorted transmission of the pressure signal, the measuring chain must have a rise-time short in comparison with the pressure rise-time in the explosions under study.

Other internal features of the autoclave are a thermocouple to monitor the initial temperature and a mixer to homogenize the gas mixture. The mixer is dispensable if gas mixtures are prepared in a separate mixing vessel. Generally, the individual components are charged into the evacuated vessel in accordance with their partial pressures; the quantities are governed by the mixture composition and the initial pressure.

Figure 11. Time dependence of pressure in a gas explosion p_{in} = initial pressure; Δp = explosion overpressure; p_{ex} = explosion pressure; $\mathrm{d}p/\mathrm{d}t$ = rate of pressure rise

Initiation trials are performed in still gas mixtures (mixer turned off) with various fuel concentrations. Analysis of each separate run with a given fuel-gas content yields an explosion pressure value (maximum on the $p-t$ curve) and a rate of pressure rise (slope of the steepest tangent to this curve, Fig. 11). Analysis of the digitally stored curves can conveniently be done by computer. Values from individual trials, plotted against the fuel-gas content, yield two curves (Fig. 12) whose maxima are the param-

eters sought, p_{max} and $(dp/dt)_{max}$ for the system under study for the specified initial pressure and temperature conditions. The maximum explosion pressure thus obtained remains virtually unchanged when the volume is increased.

Figure 12. Illustrative curves of the explosion pressure and the rate of pressure rise for a fuel – air mixture, plotted versus the fuel-gas content
Tests took place in a still gas mixture in a 14-L spherical autoclave.

If the maximum pressure is divided by the initial pressure p_{in} the result is called the maximum pressure increase factor:

$$F_{max} = p_{max}/p_{in} \tag{14}$$

Typical values for explosive mixtures with air are $F_{max} = 5 - 10$. F_{max} is more or less independent of the initial pressure, but decreases with rising temperature.

The value found for the maximum rate of pressure rise cannot be extended directly to larger volumes. The only practical way to get an acceptable value for volumes larger than laboratory autoclaves is to apply the so- called cube law, but it must not be forgotten that the validity of the law is restricted; it can be used only for volumes that do not differ too greatly in their geometry. Such a transformation is not possible if the turbulence characteristics differ, e.g., when the laboratory value is determined in the still gas mixture, as it commonly is. This must be taken into consideration in practical situations, especially when the pressure is to be relieved with blast pipes; full-scale tests may be necessary.

According to the cubic law, the maximum rate of pressure rise multiplied by the cube root of the test volume is a constant K_G:

$$K_G = (dp/dt)_{max,V_L} V_L^{1/3} \tag{15}$$

where V_L is the volume of the laboratory autoclave. The maximum rate of pressure rise can be calculated for a different volume V:

$$(dp/dt)_{max,V} = K_G V^{-1/3} \tag{16}$$

The pressure increase factor and K_G value can now serve as a basis for analyzing design practices, regardless of the fuel content in the explosive mixture in the actual plant. (Note that the spherical autoclave can be replaced by a different ignition vessel if the new vessel has the same volume/area ratio as the sphere. For example, a cylindrical vessel can be employed if its diameter and height are equal.)

2.2.2.4. Pressure Limit of Stability for Unstable Gases

There are gaseous compounds whose thermodynamic and/or chemical properties enable them to decompose explosively, without any air or oxygen, if an ignition source is present. A thermodynamically unstable compound can be prepared by direct synthesis from the elements only if energy (specifically, the free enthalpy of formation) is supplied. If such a compound (e.g., acetylene, nitrous oxide, ethylene) decomposes to its elements, energy equal to the free enthalpy of formation is released [57]. Thermodynamically stable compounds with a negative free enthalpy of formation can also decompose to compounds of lower molecular mass if the sum of the free enthalpies of formation of the decomposition products is more negative than the free enthalpy of formation of the starting substance (e.g., ethylene oxide, tetrafluoroethylene). The features responsible for the ability of thermodynamically stable compounds to decompose are “weak bonds” between atoms in a molecule, where the molecule can dissociate if its vibrations are strongly excited (e.g., by absorption of external energy). Organic molecules with multiple bonds between carbon atoms are susceptible because of the diminished binding forces at these sites. Thus there are two factors, one thermodynamic and one structural that suggest

an ability to decompose. A gas with both kinds of instability (e.g., acetylene) is most likely to decompose.

Fortunately, an unstable gas does not decompose spontaneously. The free enthalpy of activation ΔG^{A}, must be supplied to initiate the reaction. Only when the energy threshold ΔG^{A} has been overcome (Fig. 13) the reaction can proceed, with the release of the free enthalpy of reaction ΔG_{r} [58]. Such reactions become dangerous if the enthalpy of reaction is evolved so rapidly that it can no longer be absorbed by the surroundings, but remains in the system in some form. The reaction products can be heated up so that the pressure rises (in the same way as in a gas explosion involving oxygen). The energy threshold ΔG^{A} is overcome more easily the higher the pressure and/or temperature of the gas. For safe handling of gases tend to decompose, it is urgently necessary to know the pressure and temperature limits such that the energy threshold cannot be exceeded, even by a strong ignition source. These limits can be determined only by experiment.

Figure 13. Energy diagram of a decomposition reaction

The apparatus described in Section 2.2.2.3 is well suited to studies of this kind. By performing a series of ignition trials, the researcher seeks to determine the pressure, as a function of temperature, at which it just becomes impossible to initiate decomposition. The result is the pressure limit of stability as a function of temperature. To provide at least approximate statistical support for the limit, the test is replicated five times. Figure 14 shows the pressure limit of stability for ethylene at 100 – 200 °C [59].

To deal with problems relating to the safe transportation of unstable gases, studies of the kind just described are run, up to 70 °C. Pressure limits of stability at even higher temperatures are of interest in view of operations in chemical plants. It is also often desirable to find out how the pressure limit of stability can be modified by the addition of a stable gas (not necessarily inert) or what amount of foreign gas must be added to render the system stable under the operating conditions. All these questions can be answered by experiments with the laboratory apparatus described.

Figure 14. Pressure limit of stability for ethylene as a function of temperature, ignition power 1 kW

In practice, an adequate margin of safety relative to the pressure limit of stability must always be maintained when working with unstable gases.

2.2.2.5. Ignition Temperature, Ignition Energies

Explosive systems are characterized by certain parameters (LEL, UEL, $[\mathrm{O}_{2\max}]$, $p_{\max}$, $(\mathrm{d}p/\mathrm{d}t)_{\max}$, K_{G}) that can be employed in the design of explosion-protection measures. Two approaches to explosion protection are to prevent explosive mixtures from forming, and to insure safe handling of such mixtures by explosion-proof design with or without pressure relief. In a similar way, the sensitivity of these systems to ignition by certain ignition sources is described in terms of parameters that can be used in safety design (elimination of ignition sources).

It is also important in practice to find a parameter that characterizes fuels with regard to the propagation of explosions, for example, through

narrow gaps. The propagation of an explosion from a part of the plant featuring explosion-resistant design into upstream or downstream sections that are not so designed, or that are not vented, must be effectively prevented.

One such parameter is the ignition temperature, which makes it possible to assess the effectiveness of a hot surface (e.g., a motor winding) as an ignition source. Others are the minimum ignition energy, used for evaluating electrostatic (capacitive) discharges, and the minimum ignition current, for evaluating electrical (inductive) sparks. Finally, the ability of exploding gas mixtures to propagate through a narrow gap is characterized by the maximum experimental safe gap (MESG), which can be used in the design of flame arresters or "pressure-resistant" enclosed electrical equipment (see EN 50 018).

Figure 15. Apparatus for determining the ignition temperature (DIN 51 794)
a) Observation mirror; b) Thermocouple, FeCo; c) 200-mL Erlenmeyer flask; d) Heating; e) Resistance thermometer (Pt-100); f) Thermal insulation

The ignition temperature T_I is the lowest temperature of a hot surface at which a fuel – air mixture of the most easily ignitable composition can just be stimulated to burn with a visible flame. Two crucial points for determination of T_I are the geometry of the test vessel, which must provide a temperature field as closed as possible, and the formation of steep fuel concentration gradients when the fuel is admitted to the oxidizing gas phase already present in the vessel. The standard method of IEC 79-4 (embodied in DIN 51 794 and ASTM D 2155) takes these points into account. The glass ignition vessel (a 250-mL Erlenmeyer flask) is charged with air or another oxidizer. The fuel is admitted to the vessel through an inlet tube (for gaseous substances) or dropwise (for liquids; Fig. 15). The criterion for ignition is a flame forming in the vessel, which can be observed with mirrors.

On the basis of the ignition temperatures in air, fuels are placed in temperature classes (EN 50 014/5.78, DIN VDE 0165; Table 7). Ignition temperatures and temperature classes have been tabulated [42]. The maximum surface temperature T_{max} associated with a given temperature class must not be exceeded by explosion-resistant electrical (and other) equipment belonging to the class (EN 50 014, pr EN 1127).

Table 7. Temperature classes according to EN 50 014

Ignition temperature∗, °C	Temperature class	Maximum surface temperature, °C
$450 < T_I \leq 600$	T 1	450
$300 < T_I \leq 450$	T 2	300
$200 < T_I \leq 300$	T 3	200
$135 < T_I \leq 200$	T 4	135
$100 < T_I \leq 135$	T 5	100
$85 < T_I \leq 100$	T 6	85

∗ Measured according to IEC 79-4 (e.g., DIN 51 794).

When determining the ignition temperatures T_I of fuel mixtures, it must be kept in mind that there is no linear relationship between the concentration ratio (or mole fraction) of the fuels and the ignition temperature for the mixture [46], [60]. T_I values for fuel mixtures must therefore be determined for every individual case. Ignition temperatures for a given fuel in oxidizing media other than air may sometimes be quite low. This is especially so for pure oxygen and chlorine, in which T_I may be lowered by as much as hundreds of kelvins: T_I (toluene, air) = 535 °C, T_I (toluene, Cl_2) = 175 °C. This effect with pure O_2 can be accounted for by the lack of a diluting inert gas; in other cases, e.g., Cl_2, the ignition temperature is lower because the Cl_2 molecule has a much smaller dissociation energy than O_2. Also, T_I generally decreases with increasing when initial pressure [60].

The minimum ignition current, used as a measure of the igniting ability of electrical (inductive) sparks, is a fuel-specific parameter. It is the smallest current flowing in a circuit of a certain inductance, such that the spark produced

when the current flow is interrupted (in an explosive mixture of optimal ignitability) just ignites the mixture. If the minimum ignition current is known, electrical circuits can be designed so that no igniting sparks are created by switching, or on failures such as a short- circuit. This design approach is employed in explosion-resistant electrical equipment rated "intrinsically safe" (i; see EN 50 020).

The minimum ignition energy is the smallest amount of energy, stored in a capacitor, that is just sufficient, when discharged across a spark gap, to ignite the most ignitable explosive mixture. It is a fuel-specific parameter. As a measure of the effectiveness of capacitive sparks to ignite mixtures, it is particularly useful in the evaluation of electrostatic ignition sources.

Figure 16. Apparatus for determining the maximum experimental safe gap
a) Gap adjustment; b) Outer chamber; c) Observation window; d) Gap; e) Ignition source; f) Inner chamber

The minimum ignition current, the minimum ignition energy, and the maximum experimental safe gap (MESG) make it possible to rank fuels with allowance for the ability of explosive mixtures to propagate initiating action through a narrow gap.

The apparatus for determining the MESG is shown in Figure 16. It consists of two chambers connected by an annular gap of constant length (25 mm) and variable width. The two chambers and the gap are filled with an explosive mixture of the most sensitive composition. After ignition in the inner chamber (ca. 20 cm^3), the presence or absence of a flame breaking through into the outer chamber is determined visually (cf. IEC 79-1 A).

On the basis of the MESG, fuels are classed into explosion groups (EN 50 014, DIN VDE 0165): I (CH_4; only relevant for hazards due to firedamp); II A (e.g., C_2H_6); II B (e.g., C_2H_4); II C (H_2, C_2H_2, CS_2).

This knowledge makes it possible to design objects such as flame arresters, which prevent the transmission of explosions between sections of the plant, or to build explosion-resistant electrical equipment with the "flame-proof enclosure" (d) rating (EN 50018). A lamp switch housing so rated is constructed so that ignition of the mixture inside the housing does not propagate outside it; this requires the housing also to be explosion-pressure resistant.

The great advantage of being able to rank fuels is that a knowledge of the explosion group is enough for the selection of suitable explosion-resistant equipment for ignition-source elimination or explosion decoupling of certain plant sections; there is no need for costly experimental studies.

When a gas mixture contains species belonging to different explosion groups, it is necessary to determine whether the properties of the sensitive components (e.g., H_2 or other Group II C substances) govern the explosion propagation behavior of the mixture as a whole.

2.2.3. Explosion Indices of Dust-Air Mixtures

2.2.3.1. Introduction

All substances that burn in the solid state may "explode" when finely dispersed in air in the form of a dust cloud. The violence of such a dust explosion, which is best characterized by its pressure – time diagram, is similar to that of the explosion of a homogeneous gas – air mixture. In the latter, fuel dispersion takes place on a molecular level whereas in dust – air mixtures the size of the dispersed particles is typically 10 – 200 µm. Historically, dust explosions have been associated with coal mining and grain milling. Further industrialization has led to dust explosions in the chemical, pharmaceutical, metallurgical, food, and wood processing industries. All

these industries have supported research to investigate measures to prevent dust explosions, or to limit their effects [61–66].

The probability of a dust explosion is highest for very fine dusts (particle diameter < 63 µm). The upper size limit for particles forming an explosible dust cloud is ca. 400 µm. Handling or processing of coarser product may lead to the accumulation of fines (e.g., by abrasion) and thus to the formation of an explosible dust cloud.

Dust explosions may occur within apparatus in which combustible powders are handled, transported, or processed, and in which dust clouds at explosible concentrations are difficult to avoid. They may also occur in rooms with deposits of combustible powders on the floor or other surfaces when this powder is taken up in the blast wave of a primary explosion, or by some other shock wave, in the presence of an ignition source. Layers of deposited powder as thin as 0.2 mm may be sufficient to fill a room homogeneously with an explosible dust cloud.

In contrast to gas – air mixtures, which are sufficiently identified by the nature and concentration of the flammable gas, dust – air mixtures need more parameters for their exact description. Owing to gravity the particles do not stay long in suspension; the large particles settle rather quickly. Therefore, to maintain a dust cloud for a certain amount of time, and to improve homogeneity, the particles should continue to move around. A dust cloud is not normally a stationary system, but maintains a degree of turbulence which is one of the additional parameters. Others are particle size distribution (or median of the mass distribution in the case of rather monodisperse powder), water content of solid particles, and dust concentration. Ignition and explosion characteristics of dust clouds may change drastically when a flammable gas or vapor is also present (hybrid mixture).

Because of the complexity of dust – air mixtures, it is necessary to standardize methods to determine the explosion indices which describe ignition and explosion behavior.

2.2.3.2. Ignition Sensitivity of Dust Clouds

Minimum Ignition Temperature (MIT). The MIT is the lowest temperature of a hot surface at which a dust – air mixture is ignited on contact. For determination of the MIT the Godberg –Greenwald furnace or the BAM oven are used [65–67]. The Godberg – Greenwald furnace consists of an electrically heated vertical tube (Fig. 17). A dust sample is dispersed by a blast of air from a chamber containing pressurized air, and flows through the heated tube. The temperature of the tube is varied until flames are seen to emerge from the heated tube. The Godberg – Greenwald furnace is in the process of becoming an IEC standard.

a) Dust sample chamber; b) Glass adaptor; c) Ceramic tube; d) Heating coil (1 kW); e) Thermal insulation; f) Control thermocouple; g) Measurement thermocouple; h) Power; i) Mirror; j) Heat-resistant plate

The BAM oven consists of an electrically heated horizontal pipe (Fig. 18). Close to the center of the pipe there is a cap shaped impact plate to which the dust sample is blown from the outside with air. Starting at 600 °C, the temperature is gradually decreased until ignition no longer occurs.

Figure 18. BAM oven
a) Oven; b) Heating coil (1.5 kW); c) Flap; d) Test chamber; e) Deflecting surface; f) Air inlet pipe; g) Rubber bulb; h) Measurement thermocouple; i) Control thermocouple

Minimum Ignition Energy (MIE). The MIE is the lowest value of the energy stored in a capacitor which, when released in a spark discharge, is just sufficient to ignite the most readily ignitable dust – air mixture at atmospheric pressure and room temperature. No internationally accepted test method exists for determination of the MIE of dispersed powder, but an IEC standard is being prepared [68]. The dust is dispersed in a modified Hartmann apparatus (Fig. 19), a 1-m^3 vessel (Fig. 20) [66], [67], or a 20-L apparatus (Fig. 21) [66], [67]. The spark gap must be adjusted to 6 mm and the discharge circuit should meet special requirements. The inductance of the circuit should be 1 – 2 mH, except when data are to be used for assessment of electrostatic ignition hazards, when it should be $\leq 25\,\mu$H. On varying the ignition delay time

(between dust dispersion and activation of the ignition source) in the modified Hartmann apparatus, as well as the dust concentration (in all types of enclosure) the energy is always decreased by the same factor until no ignition occurs in a defined number of successive trials. The actual MIE lies between this lowest energy and the next higher energy at which ignition persists. Both values are usually reported.

a) Ignition leads; b) Bayonet closure; c) Flange; d) Thermostatically controlled heating/cooling; e) Vent; f) Measuring flange; g) Sight glass; h) Dust storage chamber; i) Outlet valve; j) Support; k) Base plate

The MIE of fine organic powders is typically ca. 1 – 1000 mJ. It decreases with increasing temperature.

2.2.3.3. Dust Explosibility

The fact that a dust cloud is not normally stationary has implications for the course of the flame front after ignition. From studies of flammable gases, it is known that any disturbance of the flame front results in an increase of the reaction interface and thus leads to an increase of the rate of pressure rise. The same is true for combustible dusts. The rate of pressure rise measured in any test apparatus therefore depends on the dust dispersion procedure and the exact moment of ignition. Knowledge of the rate of pressure rise is most important when designing explosion venting or explosion suppression. It is necessary to use a procedure for the generation of the dust cloud which can easily be reproduced, and which represents the worst turbulence characteristics that may occur in practice.

The ISO dust dispersion procedure, developed in Germany in the 1960s, meets these requirements. This procedure is used worldwide, in combination with 1-m^3 or 20-L explosion chambers. In combination with the 1-m^3 vessel, it has become an ISO standard [69]. In Germany, this dust dispersion procedure in combination with the 1-m^3 vessel or the 20-L apparatus is recommended in the VDI Guideline 2263 [67]. At CEN level, work is in progress on standardization of dust explosion indices on this basis. The dust sample is kept at high air pressure (2 MPa) in a storage container connected to the explosion chamber. For generation of the dust cloud, the powder is released into the explosion chamber via a rapid-action valve and a specially designed dust dispersion system. After a well-defined interval (ignition delay time) a chemical ignitor, located at the center of the explosion chamber, is activated, and the pressure within the explosion chamber is recorded as a function of time.

For many years the Hartmann apparatus has been used for dust explosibility tests (e.g., the closed Hartmann apparatus and the modified Hartmann apparatus). The latter (Fig. 22) has a hinged top cover. When an explosion occurs, the cover is lifted to a certain degree, depending on the violence of the explosion (i.e., the pres-

sure rise per unit time). The closed Hartmann apparatus is almost obsolete, but the modified Hartmann apparatus is still useful as a screening instrument. However, for reliable dust explosion indices (lower explosion limit, LEL, limiting oxygen concentration LOC, maximum explosion pressure p_{max}, maximum rate of pressure rise $(dp/dt)_{max}$, or the constant K_{max}, required for the design of safety measures such as inerting, explosion venting [70] or explosion suppression [71], it is necessary to use results from tests performed in accordance with the ISO standard test procedure in the 20-L apparatus or the 1-m^3 vessel.

Figure 22. Explosion pressure in an enclosure as a function of time

$$\left(\frac{dp}{dt}\right)_m = \frac{1.08\,\text{MPa}}{0.025\,\text{s}} = 43.2\,\text{MPa/s}$$

Explosion Limits (EL). The explosion limits describe the range of dust concentrations in air within which an explosion is possible. Usually, only the lower explosion limit (LEL) is determined. Owing to the rather fast settling of dust particles, the upper explosion limit (UEL) is usually not significant. It is important to note that the LEL loses its importance if deposits of fine powder are present which may become dispersed in an uncontrollable way. For the determination of the LEL of powders the 1-m^3 vessel or the 20-L apparatus are used, the former in combination with chemical ignitors of total energy 10 kJ, the latter with chemical ignitors of total energy 1, 2, or 10 kJ (the exact value is still a matter of debate). Starting with an explosible concentration, the concentration is gradually reduced until there is no longer an explosion. The dust concentration (g/m^3) at which ignition just fails over a defined number of successive trials is stated as the LEL.

The LEL can also be calculated from the heat content of the dust [72–74]. For organic powders it is typically ca. 15 – 60 g/m^3. The LEL decreases with increasing temperature and increases proportionally with increasing absolute pressure.

Limiting Oxygen Concentration (LOC). The LOC is the experimentally determined maximum residual oxygen concentration in a mixture of air and inert gas at which a dust explosion does not occur. It depends on the dust and the type of inert gas. For determination of the LOC of powders, the 1-m^3 vessel or the 20-L apparatus are used (the former in combination with chemical ignitors of total energy 10 kJ, the latter with chemical ignitors of total energy 1, 2, or 10 kJ). Starting from an oxygen concentration, at which explosion occurs, the oxygen concentration is gradually reduced, varying the dust concentration until no explosion occurs. The oxygen concentration (vol %) at which no explosion occurs over a defined number of successive trials is stated as the LOC.

For organic powders and nitrogen as inert gas, the LOC is usually 9 – 14 vol %; for fine metal powders values down to 5 vol % are reported [66]. It decreases with increasing temperature; the pressure has only a minor influence on the LOC measured in vol %.

Maximum Explosion Pressure (p_{max}) and constant K_{max}. p_{max} is the maximum explosion pressure of a combustible powder, in a closed system at optimum concentration. In spherical or cubic enclosures with the ignition source located at the center, p_{max} is independent of volume. K_{max} is the rate of pressure rise per unit time, measured in a 1-m^3 enclosure at optimum concentration. The dependence of the rate of pressure rise on the volume V is known as the cubic law (see also Section 2.2.2.3):

$$K_{max} = \left(\frac{dp}{dt}\right)_{max} V^{1/3} \tag{17}$$

This relationship is used to calculate K_{max} from results obtained in test apparatus of any volume.

Both, p_{max} and K_{max} can be determined in the 1-m^3 vessel or the 20-L apparatus with chemical ignitors of total energy 10 kJ located at the

center. The dust cloud is generated according to the ISO standard procedure and ignited after a well-defined ignition delay time. The explosion pressure p_m is measured as a function of time (Fig. 22). Such explosion tests are performed over a wide range of dust concentration until no further increase in either p_m or $(dp/dt)_m$ is observed. From a plot of p_m and $(dp/dt)_m$ against dust concentration, the final quantities p_{max} and $(dp/dt)_{max}$ are determined (Fig. 23).

Figure 23. Explosion pressure p_m (A) and $(dp/dt)_m$ (B) as a function of dust concentration
Maximum explosion pressure 1.08 MPa; maximum rate of pressure rise 43.2 MPa/s.

Fine organic powders usually have p_{max} ca. 0.6 – 0.9 MPa, and K_{max} ca. 5 – 30 MPa m s^{-1}. Very fine aluminum powder may have p_{max} up to 1.3 MPa and $K_{max} > 100$ MPa m s^{-1}. Substances are classified in accordance with their explosion violence, as expressed by K_{max}, tabulated as follows:

K_{max}, MPa m s^{-1}	Dust explosion class
<0 – 20	St 1
20.1 – 30	St 2
>30	St 3

Determination of p_{max} and K_{max} by the standard procedure described is the decisive test of whether a powder can be ignited at all in the form of a dust cloud.

p_{max} increases proportionally with increasing absolute pressure at least up to 1.1 MPa initial absolute pressure. For K_{max} this is true only up to initial pressure 0.2 – 0.4 MPa; p_{max} decreases with increasing temperature, and the effect of temperature on K_{max} cannot generally be predicted.

2.2.4. Characterization of Explosive Condensed Substances

2.2.4.1. Introduction

Explosions can occur in the gaseous phase as well as in the liquid or solid phase. Three types of explosions have been defined in Chapter 1.

- Explosions due to spontaneous decomposition
- Explosions due to spontaneous combustion
- Thermal explosions

Gas-phase explosions (due to spontaneous combustion) and the thermal explosions are described in Sections 2.2.2, 2.2.3, and 2.3. This section discusses condensed explosive substances which are likely to undergo explosions due to spontaneous decomposition.

2.2.4.2. Chemical Nature and Definition of an Explosion

A condensed-phase explosion is defined as an exothermic chemical reaction, during which gases and vapors are formed at such a high rate as to have destructive effects on their surroundings. Fragments, projectiles, ground and air shock waves are produced by the high temperature, pressures, and rates of pressure rise. The extent of damage depends on the type and the mass of the explosive substance as well as on the nature of the surroundings.

An explosive reaction can be initiated only in substances which have a high positive heat of formation or a high negative heat of decomposition. Such substances usually have a defined chemical structure. Being organic in nature and possessing, in most cases, reactive groups

with available oxygen, they can undergo intramolecular oxidation of the combustible part. Examples of oxidizing reactive groups are nitro, nitroso, and peroxy groups, but organic compounds containing azide, acetylenic, or diazonium groups may also be powerfully explosive substances. Explosive compositions may also be produced by mixing inorganic oxidizing substances with combustible materials; well-known examples are: mixtures of potassium nitrate, sulfur, and carbon (black powder); ammonium nitrate and fuel oil (ANFO); nitration mixtures containing nitric acid; and oxidation mixtures with hydrogen peroxide. Bretherick [75] and King [76] give guidance for identifying substances or mixtures as potentially explosive because of the presence of reactive groups. When a substance or mixture contains reactive groups, it depends on the molecular mass and the type and number of reactive groups, or on the oxygen balance, whether and with what intensity explosive properties are exhibited. An important difference between gas-phase and condensed-phase explosions is that in the latter the participation of oxygen from the air is not necessary.

The power of an explosion is closely related to the dynamics of gas production and energy release, as well as to the amount of gas produced and the total heat of decomposition. The energy release when a substance explodes is difficult to determine because it depends on the resulting explosion products. There may be considerable uncertainty in reported heats of decomposition of explosive substances. A slow reaction at low temperature, due to a low degree of adiabatic efficiency under the test conditions, may result in a less energetic decomposition measurement. It is known [77] that the decomposition energy measured can be an underestimate of the energy actually available. On the other hand, computer programs such as CHETAH (chemical thermodynamic and hazard evaluation [78]) can be used to predict the maximum heat of decomposition for any substance or mixture of known chemical formula and structure. As a rough guide, substances with decomposition energy > 500 J/g may have explosive properties, and those > 800 J/g may be detonable. Although this is often a good qualitative prediction of explosivity, reliable assessment of an explosive substance necessarily requires experimentally determined data.

2.2.4.3. Grouping of Explosive Substances

Explosive substances are grouped according to their intended use and/or the type of hazard connected with handling them.

When substances, because of their energy content, are used to produce explosive, initiating, propellant, or pyrotechnic effects, they are called explosives. They may be used, e.g., for blasting in rocks, coal, or salt, as initiating explosives in blasting caps (detonators), as propellant powders in ammunition, or as components of pyrotechnic articles.

All explosives are regulated internationally with respect to handling, storage, and transport. Except for international transport, this is not so for explosive substances used for chemical, scientific, or technical purposes.

According to the type of associated hazard, explosive substances (especially explosives and articles with explosive properties) are divided into groups representing:

1) The hazard of a mass explosion (mass detonation)
2) The hazard of explosions (detonations) together with the production of fragments, without the hazard of mass explosion
3) The hazard of a mass fire
4) Ordinary fire hazard

This grouping is the basis for all modern regulations and safety measures during transport and storage (e.g., safe distances).

2.2.4.4. Explosion Mechanisms

Commonly, "explosion" is used collectively for the three distinguishable mechanisms by which a substance can explode. The thermal explosion proceeds, usually in the liquid phase and more or less homogeneously, as a temperature-controlled (Arrhenius law) self-accelerating reaction (see Section 2.3). When, during the homogeneous decomposition, a temperature gradient develops, a deflagration may start at the hottest spot. It passes through the substance as a reaction front in which the heat of reaction and the reaction products are liberated. The deflagration is propagated by conductive, radiative, or convective heat transfer into the unre-

acted materials. If a substance is liable to deflagrate, this reaction can be initiated locally, e.g., by flame, heat, impact, or friction. The deflagration velocity increases with the energy content, temperature, and porosity of the substance, and exponentially with pressure. Typical values are 0.003 – 100 m/s.

The pressure dependence of the reaction velocity explains why deflagration of a small quantity of material may proceed slowly, whereas under confinement by pressure buildup, or in even larger masses by self- confinement, it occurs with explosive violence. When the speed of the gaseous deflagration products reaches sonic velocity, a shock wave develops which propagates supersonically into the unreacted substance; a deflagration to detonation transition (DDT) has taken place. Compression combined with strong heating initiates chemical reaction of the substance. Typical detonation velocities are 1000 –8000 m/s; detonation pressures reach values up to several thousand mega pascales. Detonation velocity increases with the energy content of the substance and its density. The detonation reaction may be initiated locally by heat, impact, friction, DDT, or a shock wave from other detonating substances, leading to mass explosion, and producing disastrous damage. Primary (initiating) explosives give rise to direct immediate detonation by flame, impact, or friction in quantities of a few milligrams. Secondary explosives may be detonated by primary explosives or by DDT in larger quantities. The nature of detonation is further described in the thermohydrodynamic theory of detonation [79–81].

2.2.4.5. Testing of Explosive Substances

To determine the risks associated with handling an explosive substance, experimental investigation into its individual explosive properties is imperative. Explosive properties refer to the mechanisms by which an explosive reaction can proceed, to the types of stresses and the ease with which explosions can be initiated (sensitivity), and to the power of the explosion once it takes place. Understanding the initiation, propagation, and the possibility of terminating explosive reactions, and recognition of any destructive potential form the basis for safe handling of an explosive substance [82]. The sensitivity of an explosive substance is of special importance since, if it is too high, it may preclude some or all modes of technical handling.

For several decades, explosive properties have been described by test data determined by standardized test methods [83], [84]. The latest and most comprehensive collection of tests, covering all relevant properties together with evaluation criteria for classifying explosive substances for the purpose of transport, is given in the UN Test Manual [85]. In Part I, the Manual contains test methods and criteria, together with a classification flowchart, for deciding whether a substance or mixture is an explosive substance or article of Class 1 of the UN Recommendations on the Transport of Dangerous Goods [86], and which division of Class 1 best reflects its risks during transport. Part II of the Manual presents tests methods, criteria, and a flowchart for evaluating organic peroxides and self-reactive substances (Divisions 5.2 and 4.1 of the UN Recommendations) for explosive properties.

The Manual includes ca. 70 test methods on laboratory and field scale for the substances (packed as for transport). The test methods are related to the properties to be identified:

– Detonability by shock wave, including sensitivity to detonation shock of variable strength, detonation velocity, and sensitization by cavitation (gas bubbles)
– Deflagration after ignition in an open vessel or under confinement, determining the linear deflagration velocity or the rate of pressure rise
– DDT after ignition under confinement
– Thermal sensitivity to heating under variable defined degrees of confinement, the sensitivity being characterized by the limiting diameter of a pressure-relief vent, or by the maximum pressure and rate of pressure rise
– Sensitivity to mechanical stresses (impact and friction), determination of the sensitivity limits
– Explosive power after initiation with a blasting cap or thermal decomposition, measuring the work performed or the specific energy
– Thermal stability of explosives on storage at 75 °C, or of organic peroxides and self-reactive substances on storage under adiabatic, isothermal, or heat-accumulation

conditions, determining the self-accelerating decomposition temperature (SADT) related to the packed substances

The European Community has provisionally agreed on three methods for evaluating a substance as explosive or not. These screening methods include testing the sensitivity of substances to impact, friction, and heating under partial confinement [87]. The EC regulates the classification, packaging, and labeling of such substances for all modes of handling except transport.

2.2.4.6. Conclusions

Use of standardized test methods resulting in criteria for assessing the safety of chemical procedures and installations involving explosive substances should take special note of certain factors limiting their applicability.

It requires considerable experience to perform the tests, to modify them if necessary, and to evaluate observations correctly. Each test result should be assessed for plausibility in connection with all other results. Sensitivity does not depend on the energy content of the substance, as does the explosive power. To increase the reproducibility of test results, standardized test procedures often reflect idealized conditions. The heating rate, degree of filling of the apparatus, and the strength of confinement may greatly influence the results of thermal tests. Problems of scaling must also be addressed.

Any test result corresponds to the conditions under which it was obtained, and its validity for substances in a particular plant should be thoroughly checked. Special care should be taken before neglecting a given detonability of a substance. With respect to production in a chemical plant (excluding the explosives industry), it is imperative that initiation of a detonable substance under the conditions of handling should be impossible.

2.3. Exothermic and Pressure-Inducing Chemical Reactions

2.3.1. Introduction

The overwhelming majority of chemical reactions are accompanied by heat release, i.e., the overall change in enthalpy between the starting materials and products is negative (exothermic).

The heat produced heats up the material itself, the container (e.g., the reaction vessel), and/or the surroundings. According to the law of conservation of energy, these heat flows equilibrate in a heat balance (Fig. 24). The degree of heat dissipation depends on the heat capacity of the system itself and the heat removal capacity provided by the reaction vessel design and/or the latent heat of phase transitions. If the heat production rate of a chemical process exceeds the heat removal capacity of the system, and if there are no self-stabilizing boundary conditions, e.g., reaching of a boiling point, self-acceleration will occur, resulting in a "runaway" reaction. As runaway reactions are rather hazardous, it is necessary to understand the underlying mechanism, as well as the systematic experimental test procedures to assess the hazard potential for a runaway, and to know the design criteria for safe processes in order to prevent runaway scenarios from occurring.

Figure 24. Schematic representation of heat balance [88]

2.3.1.1. Exothermic Reactions: Runaway Potential

To assess the runaway potential of a chemical system it is necessary to understand the basic physicochemistry and its interaction with the transport phenomena of heat, mass, and momentum, which determine the behavior of the system, including the reactor. The hazardous character of a chemical reaction is determined by the

Table 8. Typical heats of reaction for common chemical processes [89]

Reaction type	ΔH, kJ/mol	Reaction type	ΔH, kJ/mol
Neutralization (HCl)	− 55	Hydrogenation (nitroaromatics)	−560
Neutralization (H_2SO_4)	−105	Amination	−120
Diazotization	− 65	Combustion (hydrocarbons)	−900
Sulfonation	−105	Diazo-decomposition	−140
Nitration	−130	Nitro-decomposition	−400
Epoxidation	− 96		

overall heat of reaction (thermodynamics), and the rate of heat production (strongly influenced by the kinetics). Typical values for heats of reaction are summarized in Table 8. The total heat output of a real system can only be influenced by the concentration of the reacting materials. In the sense of a primary method to prevent runaway reactions it can be stated that the more dilute a system the smaller is its runaway potential. The disadvantage of this rule, besides its effect on the economics of the process, is the environmental consequence of a higher demand for auxiliary materials and energy consumption for their recovery. Consequently, an inherent runaway potential has to be accepted, but must be adequately controlled, either kinetically (e.g., by choice of process temperature), or technically (by reactor design).

Figure 25. Semenov (uniform) and Frank-Kamenetskii (nonuniform) temperature profiles

As already mentioned, control of chemical heat release depends on the ability of the system to dissipate this energy. Mathematically this is formulated as a heat balance, including an accumulation term as well as the heat generation and dissipation terms. Appropriate description of the dissipation terms depends strongly on the heat transport mechanism (conductive or convective, free or forced). For a uniform temperature distribution within the reaction mass, which is usually the case in well-mixed gases or Newtonian liquid, heat transfer is governed by the boundary, e.g., across a reactor jacket. This situation was originally discussed by Semenov [90].

The other extreme, nonuniform temperature distribution and heat loss governed by conduction through the bulk, is a good model for large, unstirred masses, solids, and powders and was first discussed by Frank-Kamenetskii [91]. Both cases are shown in Figure 25. For more detailed discussion of self-heat models see [92].

For phenomenological discussion of runaway reaction systems the Semenov model [90] is the more adequate. It assumes a chemical reaction $A \rightarrow B$ with an indefinite amount of initial material, so that its consumption may be neglected. It is further assumed that the temperature dependence follows the Arrhenius relationship. Based on this pseudo-zero-order kinetic approach, the heat production rate $\dot{Q}_R$ is governed by an exponential dependence on temperature:

$$\dot{Q}_R = V\,(-\Delta_R H)\,k_\infty c_{A,\infty} \exp\left(-\frac{E}{RT}\right) \tag{18}$$

The rate of heat removal $\dot{Q}_C$, assuming the coolant has Newtonian properties, depends linearly on the driving temperature difference between the uniform reaction mass temperature and ambient (jacket) temperature:

$$\dot{Q}_C = U\,A\,(T_R - T_A) \tag{19}$$

The controllability of the heat production rate can best be explained by plotting the two heat flows (Eq. 18 and 19) as a function of temperature (Fig. 26). Three different cases can be discussed: with two, one, or no intersections. These three cases can be obtained either by varying the ambient temperature (Fig. 26) or by varying the slope of the heat removal lines (equal to the product of heat transfer area and overall heat transfer coefficient). The intersections represent pseudo-steady-state conditions. In case

1 (low T_A), small deviations from the steady state, represented by the lower of the two intersections, automatically result in a return to the origin, as can easily be deduced from a comparison of the relative magnitudes of the two heat flow terms. This operating point is rated "stable". With respect to the upper steady state, once a temperature deviation occurs, the original operating conditions are never reached again. In the case of a temperature decrease, the process quickly approaches the lower steady state; for a temperature increase, the heat production rate always exceeds the heat removal capacity of the system. This leads to an unhindered self-acceleration of the reaction rate and thereby of the heat production rate (thermal explosion or runaway reaction). The same is true for all operating conditions of case 3 (high T_A). Case 2 (medium T_A) represents the limiting case of the first occurrence of an unstable operating point, characterized by the equality of rates and their temperature derivatives. From these characteristics, it can be shown mathematically that, as long as the following relation holds:

$$\frac{RT_R^2}{E} > T_R - T_A \tag{20}$$

runaway conditions need not be expected. This may be regarded as a first rule of thumb for the safety assessment of chemical processes. More sophisticated design criteria, presented in 2.3.1.4 and Section 2.3.3.1, extend the stability discussion of chemical processes from this pseudo-steady-state approach to a discussion of dynamic stability.

Figure 26. Semenov plot
1) Low T_A; 2) Medium T_A; 3) High T_A

2.3.1.2. Causes and Consequences of Overpressure-Inducing Exothermic Reactions

If the defined operating conditions do not include extensive overpressure, as is common for a number of petrochemical processes and hydrogenations, the sudden and unexpected occurrence of overpressure must be regarded as hazardous. The discussion of causes and consequences of a pressure increase must begin with a distinction between effects related to gas-generating chemistry and those related to process design.

For chemistry-related effects, the prime cause of overpressure is the formation of noncondensable gases. These may be reaction products of the desired process or of secondary reactions initiated at the elevated temperatures due to a runaway. For the first category, the basis of a suitable safety assessment is a fundamental understanding of the chemical process. Many common chemical reactions produce large amounts of gases, e.g., reductions with $LiAlH_4$ or substitutions of NH_2 groups by halogens via diazonium intermediates. Less obvious processes are those where the gas is formed in parallel reactions, e.g., the formation of gaseous ethylene oxide from 2- chloro-1-ethanol in the presence of a strong base. Provided that the reaction has been properly identified, these kind of gas-generating processes are controllable by conventional means, as their generation rate is kinetically controlled.

The most important class of gas-generating processes are decomposition reactions. These are initiated, e.g., when a runaway reaction raises the operating temperature so that the decomposition reaction overwhelms the desired reaction, or when cooling medium comes into contact with the reaction mixture, owing to a jacket or pipe rupture. Many of such undesired reactions stoichiometrically produce more than 1 mol gas per 1 mol initial material, which accelerates the pressure increase dramatically. In these cases, the process cannot be controlled and only mitigating measures can help reduce the consequences. It is therefore important to assess the process in all conceivable fault conditions, in order to initiate appropriate process or plant modifications to make the process inherently safe,

or to define suitable preventive measures as the second best choice.

Figure 27. Process hazard and safety evaluation (PHASE)

2.3.1.3. Processes Hazard Assessment and Safety Evaluation for Exothermic Reactions

Process hazard assessment and safety evaluation (PHASE) [93] is a mandatory procedure to assure safe manufacturing of chemicals. The PHASE procedure has two characteristics:

1) It has to follow predefined systematic pathways to optimize its efficiency to identify as many hazardous situations as possible, and to assure the implementation of recommended safety measures
2) It is not performed once and for all, but should be used repeatedly during the lifetime of a plant or process

PHASE has to be applied to differing degrees, depending on the status of development of a process. Preliminary assessments should be performed on laboratory scale. The first fully comprehensive application of PHASE is recommended before the first run, on pilot plant scale. Later it should be repeated whenever a process scale-up or process/plant modifications are intended.

PHASE is a stepwise iterative procedure (Fig. 27). It starts with an assessment of all chemicals, together with operating and plant conditions, for the desired process. If hazardous situations are identified at this stage, process or plant modifications have to be initiated. Experimental methods and evaluation criteria for this purpose are the subject of Sections 2.3.2 and 2.3.3. If the desired process is rated as safe, possible fault conditions and process deviations have to be identified and evaluated. If the implementation of technical or organizational preventive measures cannot assure safe operation, further process or plant modifications become mandatory, and assessment of the normal operating conditions has to be repeated, accounting for the changed parameters. This is the iterative part of PHASE. For the second step in PHASE, tools such as HAZOP, fault trees, or FMEA are recommended (see Section 3.3).

2.3.1.4. Hazard Characteristics of Exothermic Processes due to Process Design

Chemical reaction engineering principles form the basis of an understanding of reaction hazards originating from process design. Basically three different designs can be distinguished: continuous, semicontinuous, and batch. A detailed discussion of reactor design principles is given in the standard textbooks [94], [95]. This section reviews those characteristics which have a direct impact on the hazard assessment of exothermic processes.

Design and safety criteria depend strongly on whether the system is homogeneous or heterogeneous. Heterogeneous processes depend on a much larger number of parameters (e.g., particle size distribution, surface area, and porosity for

solid – liquid systems, or mass transfer parameters for liquid – liquid systems). For a detailed discussion of heterogeneous processes see [94], [95]. The following discussion is for homogeneous systems only.

Continuous processes are performed either in continuously stirred tank reactors (CSTR) or plug-flow tube reactors (PFTR). Phenomenologically, the longitudinal spatial coordinate of the PFTR is equivalent to the time coordinate of a batch process. Therefore, with respect to continuous processes, the following discussion focuses on CSTR. Continuous processes have two major advantages: the reaction rate can be controlled by the reactant feed stream; the reaction products and the solvent immediately dilute the initial materials entering the reactor. Both characteristics influence the effective concentration of reacting materials directly and reduce the thermal potential. The problem areas with CSTR are the correct design of the start-up procedure and the avoidance of dynamic instabilities. Additionally (but not of primary importance to hazard assessment), continuous processes require a larger reaction volume than discontinuous processes to achieve the same space – time yield. It is recommended to start up a CSTR as a semicontinuous process, up to the point where the expected stationary extent of reaction is achieved, and then to start the second feed stream. To avoid ignition/extinction and oscillatory phenomena, design criteria are available in [94], [95], which can easily be applied, provided the thermal kinetics of the overall process have been determined appropriately, e.g., by reaction calorimetry.

The true batch process represents the other extreme of reactor design. Batch reactors are often preferred in the fine chemicals and pharmaceutical industries because of the smaller amounts of substance handled. From a hazard evaluation viewpoint, batch processes are the most difficult, as all reacting materials are charged initially, so that the total hazard potential is present in the reactor right from the beginning. Depending on plant or process design, batch reactors (BR) can be operated either isothermally, under computer control, or isoperibolically, i.e., with a coolant kept at constant temperature (Fig. 28). In the first case, the assessment must focus on the maximum heat rate developed, ideally at $t = 0$. If the coolant temperature can be rapidly lowered by the control system, quasi-isothermal conditions can be achieved. On the other hand, sensitivity analyses by SEMENOV and others suggest, that the cooling temperature difference should not be too great [96]. There are four engineering numbers, which can be used to give guidance on safe operability: the adiabatic temperature increase ΔT_{ad}; the thermal reaction number B; the dimensionless reaction rate Da (Damkoehler number); and the modified Stanton number St (dimensionless cooling capacity of the system):

$$\Delta T_{\mathrm{ad}} = \frac{(-\Delta_{\mathrm{R}} H)\, c_{\mathrm{A0}}}{(-\nu_{\mathrm{A}})\, r c_{\mathrm{P}}} \tag{21}$$

$$B = \frac{E \Delta T_{\mathrm{ad}}}{R T^2} \tag{22}$$

where ν_{A} is the stoichiometric coefficient of the limiting component.

$$Da = \frac{(-\nu_{\mathrm{A}})\, r_0 t}{c_{\mathrm{A0}}} \tag{23}$$

$$St = \frac{U A t}{V r c_{\mathrm{P}}} \tag{24}$$

Figure 28. Batch reactor operating modes
(A) Isothermal; B) Isoperibolic
Full lines, internal temperature; dotted lines, jacket temperature.

If $\Delta T_{\mathrm{ad}} < 50\,\mathrm{K}$ and $B < 5$, isothermal batch process can be operated safely. Such processes

may be regarded as inherently safe, acknowledging that possible plant hazards are excluded from this assessment.

Under isoperibolic operating conditions, the hazard assessment focuses on the maximum temperature difference, which, under these conditions, occurs some time into the reaction. Additionally it has to be assessed whether or not the maximum reaction temperature exceeds a limiting value, which represents the temperature level at which undesired reactions become dominant. It is also necessary to assess the sensitivity of this operating point to the normal variability of other operating parameters, e.g., coolant temperature or overall heat transfer coefficient. If *Da/St* $<<1$ and thereby $(T_{\max} - T_{\mathrm{A}}) < 0.15\,\Delta T_{\mathrm{ad}}$, such batch processes can be regarded as safe.

Semicontinuous processes are performed by charging one reacting component initially and feeding the second at a constant rate. Processes performed in these semi-batch reactors (SBR) combine the advantages of CSTR, i.e., control of the heat production rate by the feed rate, and of BR, i.e., the relatively small reactor volumes. These positive factors become effective only if the problem inherent to SBR design – the risk of reactant accumulation – can be prevented. Accumulation occurs if the rate of addition exceeds the rate of reaction. A SBR can be operated safely if *Da/St* >1. Provided this is assured by the process design, accumulation of the added component does not pose a hazard [97].

2.3.2. Methods of Investigation and their Systematic Application

It is the aim of safety studies either to determine whether or not a chemical process may be carried out under predefined conditions (e.g., optimal conditions with regard to yield and time), or to establish safe operating conditions with respect to temperature, pressure, concentrations, and time. For this purpose, it is necessary to make experimental investigations by appropriate test methods. Theoretical considerations may be helpful (e.g., estimation of the hazard potential of a process from the chemical equation and molecular structures), but they cannot replace experiments. Several screening methods and more detailed test methods are used in the chemical industry to obtain information necessary for the assessment of exothermic or pressurizing chemical processes [98].

Figure 29. Differential thermal analysis (DTA)
a) Oven; b) Sample; c) Reference; d) Temperature difference signal; e) Oven temperature signal

2.3.2.1. Screening Methods

Thermal Analysis. Differential thermal analysis (DTA) is a common method for the investigation of chemical reaction hazards. A sample of the material to be tested, which may be a pure compound, a reaction mixture, a residue, or a waste sample, is exposed to thermal stress. For this purpose, the sample and a thermally inert reference material (e.g., Al_2O_3) is placed in an oven. Thermal stress can be applied either dynamically by ramping up the oven temperature at a fixed rate, or isothermally in thermal aging at elevated temperatures. The difference between sample and reference temperature is recorded as a function of oven temperature or time. The recorded signal is converted to a heat flow by a calibration function. For screening purposes, linear heating rates of 1 – 10 K/min, from room temperature up to 300 – 500 °C, are widely used. To suppress the endothermic effect of vaporization and catalytic effects of the vessel material, sealed glass ampoules are often used. A more sophisticated method is differential scanning calorimetry (DSC), where the heat flux between the sample and its surroundings is recorded directly. The resulting thermogram shows exothermic and/or endothermic transitions, originating from physical or chemical effects. Integration of the signal peaks provide

the heat content of the observed transitions. The measurable beginning of the transition is called the onset temperature (Figs. 29, 30).

Figure 30. Typical thermogram of a solid
a) Melting (endothermic); b) Decomposition (exothermic)
Heating rate 3 K/min

The advantages of DTA/DSC are the use of small sample masses and the short time (1 – 3 h) required for a run. Onset temperature, peak area, and peak shape give hints on the hazard potential of a sample. It is not permitted to perform a direct scale-up of the measured values to the true chemical process or unit operation conditions. The recorded onset temperature depends critically on the measuring conditions, e.g., heating rate and sensitivity of the apparatus. Furthermore, there is no analytical control on the extent of reaction. So the area of a peak due to a chemical reaction cannot be interpreted as equivalent to the molar heat of a defined reaction. As the sample mass cannot be stirred during the experiment, the measuring conditions are not representative for heterogeneous systems. In particular, thermograms of such samples must be interpreted carefully.

Other Screening Methods. Isoperibolic calorimetry on the scale of several grams is another screening method for testing the thermostability of chemical systems, and may be used as an alternative or in addition to DTA/DSC. The calorimeter consists of a jacketed sample vessel (the jacket temperature may be programmed). The temperature difference between the sample mass and the jacket is measured and recorded as a function of jacket temperature or time. The recorded curves are evaluated similarly to DTA/DSC curves. The use of a larger sample mass (compared with DTA/DSC) and the option of stirring allows the investigation of heterogeneous systems with more success. The low mechanical stability of the sample vessel may be a disadvantage.

For a comprehensive assessment of the hazard potential of chemical systems, not only the thermal behavior, but also pressure effects in a closed vessel, or the rate of material loss in an open system, are of interest. Both effects can be measured with the help of these screening tools as a function of the sample temperature (programmed) for sample masses of ca. 50 – 1000 mg. For the interpretation of results, restrictions similar to those for thermograms apply. The results must not be scaled up directly to the true process and plant conditions.

2.3.2.2. Thermal Aging and Heat Accumulation Storage Tests

Data from thermal aging tests can be used directly for plant-scale assessment, provided the test conditions are representative of actual process conditions (e.g., quality of solid or liquid sample identical with the actual plant material, temperature and testing time identical with the process temperature and residence time). By varying the sample amount it is possible to extrapolate the experimental results for larger quantities. A sample vessel of defined size (e.g., a glass cylinder 100 – 500 mL) is stored in a drying oven at fixed temperature. Temperature sensors inside the sample detect the onset of an exothermic reaction. It is possible to eliminate the dependence of the exothermic onset on the sample mass by storing the test sample under adiabatic conditions, using so-called heat accumulation storage tests (open or under pressure). For adiabatic tests, the sample is stored in a Dewar flask with an insulating lid. A higher degree of adiabaticity is achieved by reducing heat losses to the surroundings. For this purpose, the Dewar flask is placed in a controllable oven, thereby assuring an ambient temperature equal to the sample temperature (Fig. 31).

The heat accumulation storage test provides the sample temperature – time profile under adiabatic conditions, starting at a fixed storage temperature. In evaluating the curves, it is necessary to account for the "thermal inertia" of the experimental system. Thermal inertia expresses the fact that the heat produced by the chemical reaction system is partially absorbed

by the sample container and internal components (temperature sensor, stirrer, etc.). From a heat balance viewpoint, the extent of this effect depends on the ratio of the heat capacity of the complete measuring system to that of the reaction mixture, the so- called Φ-factor:

$$\Phi = \frac{m_R c_{PR} + m_A c_{PA}}{m_R c_{PR}} \tag{25}$$

Figure 31. Adiabatic Dewar test setup
a) Oven; b) Autoclave; c) Dewar; d) Sample; e) Temperature signal; f) Pressure signal

Generally, Φ approaches unity with increasing mass of the reaction mixture. This is important as this is both demand and justification for model based mathematical correction to data obtained in small experimental tools. Figure 32 shows typical temperature – time curves for the decomposition of a substance, starting the test at different initial temperatures.

Figure 32. Typical recording of decomposition of a substance from adiabatic Dewar experiments

The handling of toxic reaction products and the repair problems are the disadvantages of the thermal aging and heat accumulation storage tests when a decomposition reaction occurs. The problem can be reduced by using smaller sample masses (< 10 g) in metallic bombs with high pressure stability. As such apparatus has a high heat-loss factor, it is necessary to use an efficient oven with accurate temperature control to minimize this heat loss.

With modern equipment, it is not necessary to predefine a fixed starting temperature for the adiabatic test. The measuring system detects the temperature at which a threshold value of the heat production rate (e.g., 1 – 2 W/kg) is exceeded, by a "search-and-wait" procedure. Evaluation of the test run yields the temperature and pressure rates as a function of temperature, as well as a thermal kinetic interpretation of the exothermic reaction under adiabatic conditions, and the adiabatic temperature increase. The temperature/pressure rate – temperature data of such an experiment (Fig. 33) can be used for designing a rupture disk or a safety relief valve.

Figure 33. Experimental self-heat and pressure rate data from an adiabatic study of an exothermic reaction

2.3.2.3. Calorimetry

The methods described usually provide information on the thermal and/or adiabatic runaway potential of batch systems. They are not suitable for studying reactions under their predefined, normal or upset operating conditions. For this purpose, reaction calorimetry is the recommended method. In a reaction calorimeter, batch, semi-batch, and continuous processes can be studied, and complex reaction procedures can be simulated (e.g., pH control, temperature or pressure control, reflux, distillation). Moreover, the effect of deviating operating conditions can be tested

(e.g., by varying the amounts of reaction components, catalyst, or solvent, temperature, loss of agitation, simulation of adiabatic conditions).

The equipment consists of a stirred glass reactor with a cooling jacket. For the investigation of reactions under pressure, special test vessels are also available. The reactor lid accommodates several measuring instruments and input/output devices. The experiment is controlled by a data processing/acquisition unit. The calorimeter can be operated isothermally (reaction temperature kept constant throughout the run), in an isoperibolic mode (jacket temperature is kept constant), in a free-programmable mode (linear temperature ramps for the internal or the jacket temperature can be defined), or in an adiabatic mode. Calorimetric evaluation is based on temperature measurements and calibration runs, to characterize the heat transfer. The evaluation yields the overall heat production rate over time of the reaction system as investigated, as well as the heat of reaction. Special evaluation techniques allow determination of the thermal accumulation potential in the reactor due to unreacted material.

Evaluation can be based on heat-flow or heat-balance algorithms. In the first case, the heat flux between the inside of the reactor and the surrounding jacket is determined by measuring the temperature difference between the reaction mass and the coolant. This kind of evaluation may be significantly in error if the overall heat transfer coefficient changes markedly during the reaction in a nonlinear way. This is especially the case for polymerization reactions, as they are usually accompanied by major changes in viscosity. This systematic error can be eliminated by running the calorimeter in the isoperibolic mode, and evaluating the heat balance for the jacket independently. However, this evaluation method is rather complex.

If the calorimetric experiment is evaluated according to the heat-balance algorithm, the liquid flow rate of the coolant and its heat capacity must be well defined and measured; otherwise, significant errors may occur.

If reactions are investigated under reflux or distillation, it is necessary that all heat flows related to the vapor phase are accounted for appropriately. Figure 34 shows a typical apparatus for reaction calorimetry. The information obtainable from reaction calorimetry is of great use, not only for process safety, but also for process development and optimization.

Figure 34. Typical reaction calorimetry setup
a) Thermostat; b) Controlling unit; c) Reaction temperature; d) Jacket temperature; e) Quality measurement

2.3.2.4. Systematic Testing

Some 25 different experimental techniques are commercially available for the investigation and characterization of exothermic reactions. It has to be emphasized that there is no comprehensive method; it is sensible to apply more than one method to obtain the necessary PHASE data. On the other hand, PHASE demands a systematic procedure, so a certain ranking of the different techniques is required. This can be achieved by considering the life cycle of a chemical process. Researchers usually carry out their experiments on the 1-g scale; thorough experimental hazard characterization is not required, as possible consequences of events are limited to the fume cupboard, provided occupational health and safety recommendations have been strictly followed.

Process development on the 1-kg scale represents the first milestone of the process life cycle, where the preliminary PHASE should be performed, based on screening test data. Before the first run of a process in a pilot plant, the first comprehensive PHASE is required. This can only be performed reasonably if it is based on data which are not subject to large model-based, scale-up corrections; reaction calorimetry and Dewar tests are the recommended techniques [99].

For intended plant or process modifications, selection of the appropriate experimental test methods depends on each individual case, and no general recommendations can be given.

2.3.3. Assessment Criteria

The incident risk is defined as the product of incident severity and its probability of occurrence. Hence, risk assessment includes both severity and probability. In the following, a generalized procedure for risk assessment of runaway reactions with special emphasis on evaluation criteria is presented.

2.3.3.1. Runaway Scenario

It is assumed that a batch reactor is being operated under normal operating conditions, and a cooling failure occurs. Provided that unconverted material is still present in the reactor, the temperature increases, owing to the heat output related to completion of the reaction. This temperature increase is proportional to the amount of unreacted material. The temperature reached at the end of this period is called the maximum temperature of the synthesis reaction (MTSR). At this level, a secondary decomposition reaction may be initiated (Fig. 35). The heat produced by this undesired reaction leads to a further increase in temperature [100].

Figure 35. Runaway scenario
a) Runaway of desired process; b) Runaway of undesired process
1 = time to cooling failure; 2 = ΔT_{ad} due to unreacted material (for desired reaction only); 3 = ΔT_{ad} due to decomposition; 4 = $T_p - T_{initial}$; 5 = time to reach MTSR; 6 = adiabatic induction period

The following questions help to characterize the runaway scenario and to provide data for risk assessment:

1) Can the process temperature be controlled by the cooling system?
2) What temperature can be reached after runaway of the desired reaction?
3) What temperature can be reached due to runaway of the decomposition reaction?
4) Which moment of a cooling failure will have the worst consequences?
5) How fast is runaway of the desired reaction?
6) How fast is runaway of the decomposition at MTSR ?

This type of scenario should be worked out for the different possible process deviations, e.g., charging errors or higher accumulation due to loss of agitation. It allows assessment of the sensitivity of the process to these deviations.

2.3.3.2. Severity: Adiabatic Temperature Increase

Most reactions in the fine chemicals industry are exothermic. In the case of a cooling failure, or if heat removal is not sufficient to compensate for the heat production, the temperature increases proportionally to the heat of reaction. Thus, the reaction energy is a direct measure of the severity of a runaway, i.e., the destructive potential. It is usually expressed as the adiabatic temperature increase ΔT_{ad}.

Figure 36. Adiabatic runaway temperature profiles
a) – d) increasing rates of temperature increase with increasing energy

Independent of its meaning for characterization of the hazard potential and determination of attainable temperature levels, the adiabatic temperature increase assists estimation of the dynamics of a runaway. As a general rule, high energies result in fast runaway or thermal explosion, while lower energies ($\Delta T_{\mathrm{ad}} < 100\,\mathrm{K}$) result in slower temperature increase rates (Fig. 36), given the same activation energy and initial heat release rate [89].

The heats of common industrial synthesis reactions are often of the order of -100 kJ/mol, whereas decomposition reactions may reach far higher levels, e.g., -400 kJ/mol for mononitrated aromatic compounds. In many cases, the desired reactions are not themselves inherently dangerous, but decomposition reactions may lead to dramatic effects. The consequences of a runaway event can be manifold. One possibility is solvent evaporation with the subsequent possibility of a vapor cloud explosion, if the boiling point of the system is reached. Another possibility is formation of gaseous products from a decomposition reaction, which leads to a pressure increase and the risk of vessel rupture. In practice, three levels – low, medium, and high – are sufficient for assessment the severity:

Low:	$\Delta T_{\mathrm{ad}} < 50\,\mathrm{K}$, no pressure buildup
Medium:	$50\,\mathrm{K} < \Delta T_{\mathrm{ad}} < 200\,\mathrm{K}$
High:	$\Delta T_{\mathrm{ad}} > 200\,\mathrm{K}$

2.3.3.3. Probability and Kinetics of a Runaway

There is no direct quantitative measure for the probability of occurrence of an incident, or in the case of thermal process safety, for the occurrence of a runaway reaction. But, if a runaway, anticipated to occur within several minutes, is compared with one expected to occur over several hours, it is obvious that in the first case there is very little time to take preventive measures, whereas in the second case there is time to regain control of the reaction. The probability of runaway is higher with a fast than with a slow temperature increase. While quantification of probabilities is not easy, at least a comparison is feasible.

To assess the probability of occurrence of a decomposition reaction, it is necessary to characterize its kinetics. The concept of time to explosion or $\mathrm{TMR_{ad}}$ (time to maximum rate under adiabatic conditions) is of great help [98]. It can be estimated by the following equation:

$$\mathrm{TMR_{ad}} = \frac{c_{\mathrm{p}} R T_0^2}{q_0 E_{\mathrm{a}}}\ (\mathrm{s}) \tag{26}$$

where c_{p} is the heat capacity of reaction mixture ($\mathrm{J\,kg^{-1}\,K^{-1}}$); R is the gas constant, $8.31431\,\mathrm{J\,mol^{-1}\,K^{-1}}$; T_0 is the initial temperature of the runaway (K); q_0 is the heat release rate at T_0 (W/kg); and E_{a} is the activation energy (J/mol).

This equation was derived for zero-order reaction kinetics, but it can be used for reactions of higher order, provided the influence of concentration on the reaction rate can be neglected. This approximation is particularly valid for fast, highly exothermic reactions.

The isothermal mode of DSC provides an easy way to measure the kinetic parameters in the $\mathrm{TMR_{ad}}$ equation [89]. A set of isothermal experiments is run at different temperatures. The natural logarithm of maximum heat release rate, determined on each thermogram, is plotted against the reciprocal temperature in an Arrhenius diagram (Fig. 37). Runaway curves and the corresponding time to maximum rate can also be measured by adiabatic calorimetry.

In practice, three levels are sufficient for the assessment of the probability. For discontinuous chemical reactions on an industrial scale, a probability can be considered low if the time to maximum rate of a runaway reaction under adiabatic conditions is > 24 h. The probability becomes high if the time to maximum rate is < 8 h (a working shift).

These timescales are only orders of magnitude, and depend on a lot of organizational and plant design factors, e.g., degree of automation, operator training, frequency of electrical power failures, reactor size. This scaling of probabilities is valid only if safety measures in proportion to the known severity are implemented.

2.3.3.4. Assessment of Criticality

For reactions presenting a thermal potential, criticality ranking can be based on the relative values of four temperatures.

Figure 37. Determination of TMR_{ad} by differential scanning calorimetry (DSC)
A) Isothermal DTA traces: a) $T = 100\,°C$; b) $T = 110\,°C$; c) $T = 120\,°C$
B) Pseudo-Arrhenius diagram for evaluation of the isothermal runs

– $T_{process}$ (process temperature) is the initial temperature in the cooling failure scenario. In nonisothermal processes, it is defined as the temperature level at which a cooling failure produces the most severe consequences (worst case).
– MTSR (maximum temperature of synthesis reaction) depends essentially on the degree of accumulation of unconverted reactants, and therefore depends strongly on the process design [101].
– ADT 24 (temperature at which TMR_{ad} = 24 h) is defined by the thermal stability of the reaction mixture.
– MTT (maximum temperature of technical reasons), in an open system, is the boiling point. For a closed system, it is the temperature at which the pressure reaches the maximum permissible value, i.e., the set pressure of a safety valve or rupture disk.

These four temperatures permit classification of the scenarios into five different classes, from the least critical (1) to the most critical (5) [102] (Fig. 38). They are defined as follows:

1) In the case of loss of control of the desired reaction, the boiling point cannot be reached and the decomposition reaction cannot be triggered.
2) The situation is very similar to scenario (1), but if the reaction mass is kept under heat accumulation conditions for a longer time, the decomposition reaction can be triggered and the boiling point of the system can be reached.
3) In the case of loss of control of the desired reaction, the boiling point of the system is reached, but the decomposition reaction cannot be triggered. The safety of the process depends on the heat production rate of the desired reaction at the boiling point [103].
4) In the case of loss of control of the desired reaction, the boiling point is reached, and the decomposition reaction can, theoretically, be triggered. The safety of the process depends on the heat production rate of both the desired and decomposition reactions at the boiling point. Evaporative cooling may serve as a safety barrier in open systems.
5) In the case of a loss of control of the desired reaction, the decomposition reaction is triggered and the boiling point is reached during runaway of the decomposition reaction. It is very unlikely that evaporative cooling can serve as a safety barrier. The heat production rate of decomposition at the boiling point determines the thermal safety of the process. It is the most critical of all scenarios.

Figure 38. Assessment of criticality
a = T_P; b = MTSR; c = range where decomposition becomes relevant; d = *bp*

2.3.4. Measures

Three categories of measures, with different applications, are distinguished:

1) Hazard-preventing measures, which suppress the potential, e.g., dilution, change of synthesis route. These measures render the process inherently safe [101].
2) Hazard- controlling measures, e.g., change from batch to semibatch or continuous operation, interlocks in the process control system (Section 3.4.3) etc. These measures render the process fail-safe.
3) Consequence-mitigating measures, e.g., dumping, quenching, venting (Sections 3.5, 5.1).

Depending on the criticality, different measures can be applied to prevent or control the runaway or to mitigate its consequences:

1) No special measures are required, but the reaction mass should not be kept under heat accumulation conditions for long periods. Evaporative cooling serves as an additional safety barrier.
2) No special measures are required, but the reaction mass should not be kept under heat accumulation conditions for long periods.
3) The measure of choice is to use the evaporative cooling to keep the reaction mass under control. A distillation system must be designed for that purpose, and has to work effectively, even in cases of utility failures. A backup cooling system, dumping of the reaction mass, or quenching can also be used. These measures must be designed adequately and must be available immediately after the failure occurs.
4) Similar to (3). The same measures apply, but the additional heat production rate due to the secondary reaction has also to be taken into account.
5) In this case, the boiling point is very unlikely to serve as a safety barrier. Therefore only quenching or dumping can be used. Since, in most cases, the decomposition reactions release very high energies, particular attention has to be paid to the design of safety measures. It is worth considering an alternative process design, in order to reduce the severity or at least the probability. The following possibilities should be considered: reduction of concentration, change from batch to semi-batch, optimizing semibatch operating conditions to minimize accumulation [89], [104], changing to continuous operation, etc.

3. Development, Design, and Construction of Safe Plants

3.1. Objectives, Regulations, and Concerns

The goal of all plant safety effort is to eliminate or reduce the possible hazards described in Chapters 1 and 2. According to Section 1.3, this means limiting the risk created by the facility to an acceptable level. At the same time, the relevant regulations and engineering codes must be complied with. In many areas, these implicitly establish the required level of safety (or acceptable risk).

All the industrialized countries have adopted regulations to protect workers, uninvolved third parties, and the environment [105]. These regulations employ various combinations of the following approaches:

1) Setting standards for the quality of engineering facilities and their safe operation
2) Establishing approval or licensing procedures for the erection and operation of plants and for substantial modifications to them
3) Requiring regular inspections of the plant and its technical equipment by the operators, government agencies, and (sometimes) independent third parties
4) Assigning civil liability and legal responsibility for damage caused

Because there was initially little experience relating to the hazards of technology, the first regulations were written for individual types of apparatus regarded as dangerous (steam boilers, pressure vessels, machinery with moving parts) and aimed chiefly to insure occupational safety and to protect third parties. Later, regulations for other types of equipment were added, attempts were made to extend protection to new areas such as surface waters, and new regulatory principles such as the principle of precautionary action were introduced. It is not unusual that regulations are created by many independent bodies,

with very different jurisdictions. As a result, in Germany (for example) there is a rather complicated system of regulations for chemical plants, with overlaps and multiple rules, and the density and the degree of detailing of regulation differ widely from one regulation to another.

The safe design and safe operation of chemical plants in Germany are governed by regulations stemming from the following fields of law [106]:

1) Building and construction law
2) Occupational safety law (including the Equipment Safety Act, regulations defining facilities subject to supervision, and the Accident Prevention Regulations)
3) Hazardous substances law (including the Chemicals Act and the Hazardous Materials Regulation)
4) Water pollution control law (including the Regulation on Facilities with Water-Contaminating Substances)
5) Air pollution control law (including the Major Hazards Directive [107])

This complicated situation is not likely to be fundamentally changed by harmonization efforts in the European Single Market, for two reasons: First, under the EEC Treaty (Article 100 a) [108], only requirements on the quality of technical devices are subject to harmonization. Second, regulations in the European Union (EU) continue to be created, adopted, and enacted into law by the member countries according to the old pattern (e.g., for specific types of facilities).

As a rule, the regulatory system is structured vertically [109]. Legislation at high level sets forth the scope and objectives as well as the solution approaches in general form, while engineering codes and standards at lower levels are largely concerned with technical details.

Regulations, especially at sublegislative levels, are designed deterministically in that the required safety is deemed to be attained if the plant satisfies certain requirements on design, sizing and equipment. An exception can be found in a Dutch regulation under which a chemical plant, to be approved, must operate at a risk below a value described in terms of fatal accident probabilities [110].

Plant builders and operators view plant safety in terms of the types of hazard arising from the process. For them and their dealings with the authorities, it would be simpler if there were a single consistent set of regulations, broken down by hazard type (releases and spills, fires, explosions) and – instead of setting fixed technical solutions for protective tasks – such a code would use fixed solutions merely as examples of ways to achieve the stated objective.

This approach would have the advantage that the required safety could be achieved by the most advantageous technical resources in each instance. In addition to that, the "plant" orientated view would no longer require multiple specific regulations covering occupational safety and health, air and water pollution control, since one criterion for the plant (e.g., tightness) would simultaneously take care of related problems in the other areas.

The main safety tasks for the process designer and the designer and builder of process plants are:

1) To identify and correctly assess all types of hazard
2) To take appropriate steps to reduce and control these hazards

The key hazard types are those listed in Section 1.1:

Releases and spills
Fires
Explosions

The safety tasks can be broken down into the process itself and into the safe design and operation of the technical facility required for the process. The specific tasks can then be listed as follows:

1) Achieve safe process design by: a) identifying all types of hazards; b) assessing their hazard potentials; c) minimizing the hazard potentials; d) deactivating the hazard potentials
2) Achieve safe plant design and operation by: a) systematically analyzing danger sources; b) evaluating their probabilities of occurrence (usually qualitatively); c) minimizing sources of trouble and error; d) employing fault-tolerant design

In detail (see also Section 1.2), this means:

1 a) For all substances to be processed, safety ratings and toxicologically and ecologically relevant data must be acquired (see Chapter 2). A comparison of process parameters and design data with safety ratings, step by step through the process, reveals where danger sources exist, or may arise.
1 b) The magnitude of each hazard potential is evaluated through analyses, e.g., those described in Sections 1.4.2 and 1.4.3.
1 c) It must be determined whether the hazard potentials can be reduced through suitable process design.

The practices recommended here lead to inherent safety [111], [112]. To achieve this goal the planner should replace hazardous substances by less hazardous ones wherever possible. Large inventories should be avoided as far as possible, e.g., by using process steps that can be carried out quickly in a small volume, by introducing continuous operations in place of batch operations, and by eliminating large buffer volumes.

1 d) Any hazard potentials that remain must be deactivated in such a way that they cannot manifest themselves in the process. Lowering the temperature far below critical values or diluting substances and handling them in solution (to lower the vapor pressure) are the approved methods. They also help make the process inherently safe [111], [112].

If the plant is to be conceived for a process that has been safety optimized in this way, two analytical tasks, followed by two design tasks, must still be performed:

2 a) The system plant must be systematically searched for danger sources, i.e., possible defects and failures that can activate the deactivated hazard potential.
2 b) When possible faults are identified, their frequencies or probabilities of occurrence must be evaluated so that appropriate safety measures can be taken.

The last two tasks can now be undertaken with an eye to the magnitude of each hazard potential (task 1 b) and a (qualitative) measure of the probability of a defect that would activate the hazard potential:

2 c) All possibilities for minimizing sources of trouble and error must be exhausted [112].
2 d) As far as possible, the facility must be designed and equipped so that faults are "forgiven" without resulting in harm. One way to accomplish this is to use redundant (multiple) safety devices [112] (see Section 3.4.3).

In carrying out these tasks, some of the steps (2 a – 2 d) may have to be done more than once, recursively, because any change in the system due to the new measures can introduce new danger sources.

For this reason, and because the development of a process and the associated plant is done step by step, with concomitant advances in understanding a "holistic" procedure, segmented by time, technical specialty, and logical relationships, must be adopted in the development, design, construction, and operation of a chemical plant.

Examples of such methods are presented in the Section 3.2.

3.2. Procedure for Designing and Constructing Safe Plants

Chemical processes and their associated technical facilities are developed in steps. Process development in the laboratory is followed by testing of the process on a pilot scale before the project goes through the various planning stages (preliminary, draft, and detailed design). The planning process culminates in the purchase of equipment and erection of the plant. After a test and commissioning phase, the facility is put into production. The left-hand side of Figure 39 shows these stages [113].

Each phase involves questions as to the safety of the process and the plant, each of which must be answered immediately or, at the latest, before the process goes on to the next phase. The most expedient way of creating a safe plant is thus to plan for safety studies. At each step in process and plant development, safety analyses must be done (ideally integrated into the development) in order to pose the right questions and immediately seek solutions to the problems identified.

These ideas are the basis for the procedure chosen by Bayer, a large German chemical company (Fig. 39). Safety analyses are broken down into four sections, each concluding with a certificate prepared by safety experts. This certificate

Figure 39. Technical safety audit scheme for new plants or changes to existing plants (Bayer) [113]

states that the required studies have been performed, and the correct conclusions drawn from them.

The four phases of safety analysis can be listed as follows:

A 1) To create safety principles by: compiling and determining safety, toxicological, and ecological data; identifying sources of danger in the process; examining possible safety solutions; establishing the safety concept for the process
A 2) Defining the safety concept for the plant by: performing systematic analysis; identifying technical protective measures
A 3) Performing a detailed safety analysis by: analyzing all plausible forms of trouble as to cause, effect, and corrective measures; adopting the final detailed safety concept
A 4) Conducting the safety acceptance of the plant by: doing a nominal/actual comparison (concept/implementation); carrying out functional tests

This procedure is organized in an obvious way, and has the advantage that a completion certificate must be prepared at the end of each phase, before the next phase begins. The project is not released unless the planning certificate is ready, and the plant does not go on stream unless there is a safety acceptance certificate. These rules are set forth in an internal directive [114].

Similar procedures are common in other companies. They are not always so formal, but they embody the same principles and use the same resources.

BASF, for example, uses a three-phase approach for these studies [115]. Phase 1 generates a basic safety concept with provisional solutions for the main possible hazards in the process. Phase 2 involves elaboration of the safety concept, so that it can be submitted to the author-

ities along with the approval application (safety analysis, safety report). Detailed safety verification takes place in phase 3.

Hoechst utilizes the principle that certain safety analysis and design results, once created, become important documents that must accompany the process and the plant throughout their lives [116]. A substance data report and transmission report have been developed for this purpose; they function to gather key safety information and communicate it within the company; a checklist is used in the safety assessment of production facilities.

A number of publications on the performance of safety analyses have been issued by ESCIS, the Expert Commission on Safety in the Swiss Chemical Industry [117], [118]. These stress principles and organization for this kind of work, establish key points to be analyzed at various times, and include methodological aids.

Essential in all these procedures is that nothing is overlooked and the proper specialists are brought in at the proper time. All such procedures can therefore be said to regulate three things – who does what and when.

The methods employed by Degussa [119] and by Lurgi, a plant construction company [120], assign great importance to these aspects.

Over the plant's economic life, all the results of safety work are used again and again for guidance, e.g., during maintenance and plant modifications, or when new personnel are being trained. Close attention must be paid to clear and complete documentation of the safety analyses; the recommended form for this is a concise, uniform, computerized database keyed to process, process step, plant, and plant section, and covering all danger sources with causes, effects, and corrective measures (including brief justifications). It can be used directly in the writing of safety reports pursuant to the Major Hazards Regulation (Seveso Directive) [107] and can easily be consulted from the plant operating personnel whenever necessary.

By way of summary: the design and construction of safe plants calls for a highly structured and organized procedure clearly setting forth what has to be done by whom and in what way, and focusing on the creation and routing of documents. This is called a safety management system.

In accordance with this principle, it has recently been suggested in both the United States [121] and Germany [122] that "safety management" should be implemented on the model of quality management following the well known international standards ISO 9000 ff. This idea makes sense, provided the procedures recommended for quality assurance are reinterpreted for this new purpose. This tends toward the procedures discussed above, which are better suited to the legal situation, at least in Germany.

In order that nothing should be overlooked in the analyses, it is desirable to provide methodological aids to the specialists as they deal with various problems. Section 3.3 concerns such aids.

3.3. Methodological Aids

The safety concept for a chemical plant must be complete, with an answer ready for any safety question. All necessary questions which can help reveal potential sources of danger must be posed ahead of time.

The problem of a comprehensive and complete analysis comes up twice in the course of process and plant development.

First, for the process (task 1 a of Section 3.1) the safety figures for the various substances (toxicity, flammability, explosibility) must be determined. Second, for the plant (task 2 a of Section 3.1) defects and malfunctions in the system that can activate the hazard potentials must be identified.

Appropriate safety engineering involves assessing the hazards as to both possible scope (task 1 b of Section 3.1) and probability of occurrence (task 2 b of Section 3.1).

Methodological aids available for use in these tasks [123], [124] are all characterized by clear and easily understood structures and systematic procedures.

The specific methods differ in:

Objective of the analysis
Functional principle employed
Basic knowledge required
Appropriate time of use
Aids needed
Results achievable
Documentation
Cost/benefit ratio

If we go back to the four chief tasks of safety analysis

1) Completely identifying hazards due to substances (task 1 a)
2) Assessing hazards as to potential scope (determining the hazard potential, task 1 b)
3) Identifying danger sources in the plant (identifying defects and possiblities for malfunctions, task 2 a)
4) Evaluating the possible hazards with respect to probability of occurrence (task 2 b)

the methods can be placed in four groups, two relating to the identification of problems and two to their assessment.

Table 9 summarizes the most important methods. The literature refers to many more methods than those in the table. In most cases, the additional names do not refer to formal methods, e.g., "safety audit", "what-if-method", and "preliminary hazard analysis", as defined in [124]; or they are synonyms for known methods: "human error analysis", "action error analysis", and "human reliability analysis", all concerned with human errors and using checklists, keywords, tables, or event trees to study their effects; or they are combinations of two methods, e.g., "cause – consequence analysis", a combination of incident sequence analysis and fault tree analysis [123–125].

The methods of Table 9 increase in difficulty and cost from top to bottom; with the exception of consequence analysis, they are also arranged roughly in chronological order to use in process and plant development. In accordance with this ordering, the amount of input information required, the level of complexity, and the amount of special knowledge required also increase from top to bottom. Therefore assessment methods must generally be carried out by specialists, while the identification methods should be among the tools used by every chemist and engineer in the process industries, particularly the chemical industry.

The identification methods used in safety analysis are summarized below.

Checklists and Relationship Charts. A checklist enumerates points that, according to experience, are associated with hazards in the handling of substances and mixtures of substances, or in the performance of a technical process. It can be as detailed as desired, and must be suitable for the kind of analysis being carried out. For example, checklists can be developed and used for thorough analysis of all safety-relevant material properties. If the concern is whether explosions can be initiated by undesired reactions, the checklist comprises such questions as:

– Are the substances stable?
– What happens if foreign substances are admitted?
– What happens if the process parameters (temperature, concentration) change?

The formal method is to work through such lists of questions and to determine whether:

1) A hazard is possible (yes or no)
2) Further study is needed
3) Safety measures are called for

The results of the analysis can be documented directly on the checklist or on a summary form reflecting its organization.

Figure 40. Reaction matrix showing all possible pairings of substances (tests for unwanted reactions)

Checklists can be used to insure the completeness of the safety concept in later phases of a plant project, e.g., in the design phase, to insure that possible events such as power outage, cooling outage, or stirrer outage are included in the safety concept. The creation and use of checklists is also customary in plant operation. They have the obvious advantage that they can

Table 9. Safety analysis methods

Task	Aim	Working principle	Method
1) Identification of hazards	1) To complete the safety concept	1) Memory-jogging	1) Checklists
			2) Relationship charts
		2) Use of search aids and tables	3) Failure modes and effects analysis
			4) Action error analysis
			5) Hazard and operability studies
2) Evaluation of hazards according to probability of occurrence	2) To optimize safety systems with regard to reliability and availability	3) Representation of interconnections of failures in graphical form and evaluation of probability	6) Incident sequence analysis (inductive)
			7) Fault tree analysis (deductive)
3) Evaluation of hazards according to consequences	3) To minimize the hazard potential and devise optimum protective measures	4) Mathematical analysis of physicochemical processes	8) Hazard consequence analysis

be adapted to any problem; their drawback is that things not included may not always be recognized and dealt with.

The same limitation applies to the second "memory-jogging" method, the use of compatibility charts [124] or relationship charts [125]. One use for this technique is to check the compatibility of all the substances that can come into contact in a process. If, for example, there are substances A to G, then half of a two-dimensional matrix (Fig. 40) gives all possible pairings of substances.

By systematically scanning over the interaction fields, it is possible to check whether mixing two substances creates a hazard, and whether further experimental study is called for. The disadvantage of this technique is obvious: mixtures of three or more components do not appear. Caution is therefore indicated, and matrices are more often used simply to illustrate safety situations, e.g., causes and effects or effects and corrective actions [117].

Hazard and Operability Studies (HAZOP) and Similar Methods. The second group of problem-identifying methods includes:

- Failure modes and effects analysis [123], [124]
- Action error analysis [123], [124]
- HAZOP studies (called PAAG methods in Germany) [127], [128]

These methods are so similar that they can be described together. All can be characterized as "deviation analysis" in that they look for possible hazards that can arise in the process, in the plant, or in plant operation if an error occurs, or the state or sequence of actions deviates from the prescribed state of sequence. (The assumption is that there are no hazards in the prescribed state or sequence.)

In this analysis of deviations, similar forms are employed for all three cases. As a rule, the form covers the following aspects:

- Deviation (error, failure)
- Cause
- Effect
- Corrective action

In many analysis, the following are also included:

- Error detection (how?)
- Frequency (often/seldom)
- Severity of effects

The third trait common to all three methods is the use of search aids. It is here and in the objects of study that the methods differ.

Failure modes and effects analysis (FMEA) is oriented to items of equipment and machinery, each having a certain function in the plant. It employs the working hypothesis that this function is not performed, i.e., each piece of equipment is examined for the effect its failure has, and what corrective action may be required.

The search aids in action error analysis and HAZOP studies are keywords describing deviations from nominal conditions or a nominal sequence. Keywords used to characterize human errors include:

- Too early

– Too late
– Not
– Wrong object
– Wrong sequence

Typical keywords for the HAZOP method [128] include:

– More
– Less
– No
– Different from

Much has been written about this and the other methods [123–128]; Table 10 presents a few examples of analyses by all three methods for a stirred-tank reactor.

All that remains is to indicate the proper time for applying these methods. In the design of a new plant, they should come in at the detailed safety design phase, when most of the piping and instrumentation diagrams are ready. These methods are also useful in the inspection of plants already built and on stream.

In the author's view, the possibility of creating suitable keywords for all parameters, functions, and action sequences in a plant makes the HAZOP method so flexible that it can cover the full range of applications of the other techniques.

Just two identification methods are therefore of any practical importance in the development of a complete safety concept: checklist methods and the HAZOP method.

Assessment of Hazards by Consequences. The concept of the hazard potential was introduced in Section 1.3 as a way of evaluating the magnitude or severity of a safety problem. Section 1.4 described how the hazard potential can be determined and what difficulties and imponderable factors must be taken into account.

If the scope and quality of safety practices are to be suited to the hazard potential so that a generally comparable and acceptable risk level is achieved, it is necessary to get at least a rough idea of the magnitude of the hazard potential (see also Section 3.1).

On the other hand, if effect-limiting safety devices are to be custom designed, e.g., an emergency pressure-relief system or a scrubber to handle off-gases in case of an emergency, it is necessary to model the physical and chemical processes taking place during the accident and to investigate their effects. Protective systems can be tailormade, and hazard potentials can be minimized (tasks 1 b and 1 c of Section 3.1).

Evaluation of Hazards by Probability of Occurrence: Incident Sequence Analysis and Fault Tree Analysis. Both methods in this class examine links between faults, represent them graphically, and (in principle) can assign probabilities to them. Incident sequence analysis starts with a single fault, and observes how it may develop. The working hypothesis is that every safety measure can succeed or fail with a certain probability.

Figure 41 shows a simple event tree for a temperature rise in an exothermic semibatch chemical reaction where three safety measures (heating shut-down, feed cut-off, and emergency cooling) have been instituted to prevent the reaction getting out of control.

The figure illustrates the three-stage safety concept. The probability of the undesired event can be calculated if the probability of the initial event and the failure probabilities of the several safety measures are known.

More careful analysis of the sequence of events reveals that the model is far too simple for the process under discussion. Whether the safety actions succeed or fail depends heavily on the intensity and rate of temperature rise, as well as the dynamic response of each action, and these are quantities that cannot be simply described in probability terms. Therefore, the only utility of event tree analysis for such processes is that it can make relationships easy to understand in simple cases.

Similar limitations apply to fault tree analysis, at least when used for typical processes in chemical systems (Fig. 42). The analysis goes in the opposite direction to that in incident sequence analysis: deductively from an undesired event. Faults are connected from top to bottom in chains that can lead to the top event. There are two main kinds of link:

1) The blocking AND junction: more than one event must occur in order to open the path upward
2) The passing OR junction: one event from a set of several events is sufficient to lead to the next higher event

Figure 41. Event tree diagram showing success or failure of safety measures

Figure 42. Fault tree diagram

Table 10. Examples of safety analysis methods applied to a stirred-tank reactor

Method	Deviation	Cause	Consequences	Safety measure
Failure modes and effects analysis (failure of equipment)	stirrer: does not turn, turns wrong way:	no electricity, motor defective, wrongly installed	heat transfer impeded, solids precipitate	revolution counter, feed shut-off, control unit
	steam valve: does not close	jammed	temperature increase in reactor	feed shut-off
Action error analysis (human error)	"too late": steam off, cooling water in	operator not paying attention, overworked	temperature increase, danger of uncontrolled reaction	alarm, feed shut-off, emergency cooling
	"not": steam off	operator not paying attention		automatic shut-off
	"incorrect": product	mix-up	unknown reaction	labeling analysis
Hazard and operability studies (deviations in functions and process variables)	"more": steam, heat	pressure reduction fails, no cooling	temperature increase, danger of uncontrolled reaction	steam shut-off by hand, feed shut-off, emergency cooling
	"none": cooling water, stirring	valve does not open, driving mechanism defective	heat dissipation impeded, temperature increase	feed shut-off, emergency cooling
	"reverse": direction of stirrer	wrongly installed	solids precipitate	direction indicator, control unit

Both fault tree analysis and event tree analysis pose stringent requirements on correct application and interpretation. Both call for experts. The methods have been fully described in the literature [123–126] and have been standardized in Germany [129], [130]; with respect to chemical safety, however, they have so far not played a significant role, for the reasons discussed earlier. Their main area of application is in the assessment and optimization of complicated technical systems in which the components display a yes/no failure behavior with assignable probabilities, and where the failure rates are known (e.g., in aviation and space flight). For further discussion see [123], [124], [131].

It can be maintained that these methods do not provide a satisfactory basis for assessing hazards in chemical processes as to probability or frequency of occurrence. The process variables in the analyses are also functions of time and intensity, and there is not a sufficiently large number of comparable states for statistical analysis. Estimates of probabilities therefore have to be established qualitatively or semiquantitatively on the basis of experience and the number and quality of safety measures.

For the same reasons, attempts to evaluate risks from chemical plants on the basis of occurrence probabilities of single events and process and component failure rates have not yielded useful results [131]; but this is not a fatal drawback because the risk due to chemical production (Section 1.4.1) can easily be derived from historical data of long-time experience and has proved low in the past.

3.4. Safe Processing: Strategies

3.4.1. Fire Protection

3.4.1.1. Fire Prevention

The key factors governing the occurrence and impact of fires are the quantity of combustible substances and possible ignition sources present in the plant. Both factors must be determined and taken into consideration for effective design of fire-protection measures.

First, it is necessary to ascertain the form and quantity of combustible, flammable, and explosive substances located inside battery limits. As well as products, auxiliary substances, and packaging materials, thus evaluation must also include energies, construction materials, and combustible parts of the plant.

Next, these combustible substances are rated according to their key fire parameters (see Section 2.2.1). The analysis must include the state of aggregation in which these substances are held in the plant under normal or process conditions, as well as the extent to which a possible fire, by raising the temperature, can initiate further critical reactions. A crucial point is whether fire loads

are unprotected or are protected from the direct action of ignition sources by noncombustible packaging or enclosures, e.g., steel tanks or reactors [132–134].

The first important measure to prevent fires is to minimize the fire loads. In industrial plants, this can be done only to a limited extent, so possible ignition sources must also be identified, eliminated, or isolated from the existing combustible substances by bulkheads. Some examples of ignition sources are [135]:

- Open flames
- Sparks
- Compensating currents
- Spontaneous ignition
- Hot surfaces
- Electrostatic charges
- Chemical reactions
- Vibrations, shock waves
- Thermal manifestations of mechanical energy (e.g., friction)
- Thermal manifestations of electrical energy (e.g., overheating)

Ignition sources present during maintenance and repair operations also merit special attention. Sparks from welding, burning, and abrasive cutting have repeatedly caused fires. It is therefore desirable to prescribe the necessary safety precautions in safety certificates (see Section 4.4).

Smoking must be expressly forbidden in plants and warehouses. The creation of special smoking areas is preferable to concealed smoking in no-smoking areas. Appropriate containers, e.g., self-extinguishing wastepaper baskets, must be furnished for the disposal (daily if possible) of combustible wastes.

To avoid ignition by lightning, all buildings must have lightning protection. Potential compensation between large-area metal structures should be kept in mind, as should the use of overvoltage protection.

Critical effects can also follow from reactions between combustible substance and a fire-extinguishing agent. If incompatibilities lead to restrictions on extinguishing agents, these must be identified and integrated into the planning of organizational and technical fire-fighting procedures. For example, the reaction of fire-fighting water with a combustible substance may release not only flammable gases (from potassium, alkali metal compounds, etc.) but also corrosive vapors (HCl from chlorosilanes, acetyl chloride, etc.). Ignition by static discharge has caused accidents where CO_2 or medium-expansion foam has been improperly used [133], [136].

3.4.1.2. Limitation of Fire Effects

The principal effects of fire have to do with the toxic action of the smoke, and the high temperatures. To minimize harm to humans and animals, the environment, and property, a fire-protection concept must be developed for every industrial facility. The following sections identify the measures that must be included in such a concept.

Design und Construction. Access to the plant must be guaranteed by linking it to roads, streets, and fire service entries. Staircases – their number and placement dictated by the permissible lengths of escape and rescue routes – must give access to interior areas of the building. Escape and rescue routes simultaneously serve as lines of attack for firefighters, and must therefore be built to remain safely usable for an extended time. In modern industrial buildings, this is achieved by erecting massive stair towers (turrets) or administrative service wings, which are more or less independent of the supporting structure in the production building proper [137–139].

The availability of fire-fighting water is insured by a main supply designed to serve the needs of the entire developed area, and a plant supply designed to meet the special needs of the facility.

Fireproofing of the supporting beams of the building should be suited to the possible thermal loads in the anticipated fire. Simple approximations can be used for rough estimates (e.g., DIN 18 230), or more exact thermal-balance calculations can be performed. Regardless of the result, the use of noncombustible structural materials, or at least materials that burn only with difficulty or are difficult to ignite, is preferable.

An effective way to reduce temperature stress is to build in smoke and heat exhausts. Smoke extraction devices, which have to be opened mechanically, serve chiefly to remove cold smoke, and thus protect escape and rescue

routes; heat exhaust systems are intended to remove hot fumes, and thus reduce the thermal stress on the supporting members of the building. Materials that fuse in a short time can be employed effectively and economically in these devices [140], [141].

The subdivision of the plant building into fire compartments or fire-fighting compartments should prevent unacceptable spreading of the fire. This is accomplished by walls and ceilings rated for a specified fire endurance (commonly 90 min). Openings in these members must be closed off appropriately; this includes doors, windows, ventilation ducts, cable and pipe penetrations, openings for tracked conveying systems, and other weak points [139], [142].

When a building is compartmentalized in this way, care should be taken to separate areas allocated to uses, e.g., administration, production, technical zones, and storage. Storage of starting materials and end products in production areas should be avoided.

Retention of contaminated fire-fighting water must form part of the design concept for fire protection. Retention is implemented, appropriate to the purpose of the building, the water contamination class of the substances, and the protective measures employed. If facilities are available for intercepting and removing contaminated fire-fighting water, normal water-retention facilities can be erected for more than one plant or storage area [143].

Fire-Protection Equipment. When fire compartments must be very large, for reasons dictated by production aspects, or when very large quantities of combustible substances or high fire risks are present, fire-protection equipment must be installed. The selection of such equipment is governed by the fire risk. The fundamental distinction is between room-protective equipment, which covers the entire enclosed region or fire compartment, and local protective equipment, whose action is restricted to a particular unit [144], [145]:

Early fire-detection devices are connected to a continuously staffed central office (that of the fire-fighting service if possible) and give a prompt alarm to the personnel assigned to damage control, so that the time allowed for the fire to develop undisturbed is cut short. Depending on the combustile material present, smoke, heat, and flame detectors can be used.

Automatic fire-extinguishing systems involve more than mere early detection. They are connected to a continuously staffed central office, and not only send an alarm to fire-fighting personnel, but also take immediate fire-fighting action. A properly designed and constructed system can suppress a nascent fire or block its progress, so that the fire-fighting service has a better chance of success.

The design of the fire-extinguishing system must include the proper extinguishing agents carefully matched to the type and quantity of combustible substances. Restrictions on extinguishing agents, e.g., because of critical reactions of stored substances with water, must be observed.

A sprinkler system consists of fixed piping with spray nozzles, closed off by heat-sensitive elements (liquid-filled glass vessels or fusible closures, with triggering temperatures ca. 50 – 260 °C). If a fire starts, the elements above the fire site experience a thermal load, which opens the outlets of the spray nozzles so that extinguishing agent is supplied to the fire site. Because only the nozzles above the actual site of the fire open, damage by the extinguishing agent is limited. Applications include piece-goods storage areas and production areas with large quantities of combustible substances. Water sprinkler systems are suitable mainly for Class A solid fuels. Sprinkler systems with a mixture of water and foaming medium can be employed with Class A solid fuels and with combustible liquids (Class B).

A water-spray or deluge system consists of a fixed pipe grid with open nozzles. In contrast to the sprinkler system, extinguishing agent is delivered through all the nozzles at once, over the entire area of the system. The extinguishing action is stronger than that of sprinklers, but the possibility of secondary damage is greater. This type of system is generally used only where the fire spreading rate is extremely high, e.g., transformer installations or warehouses containing substances that burn very rapidly or explosively. Water and mixtures of water with foaming media can be used.

Carbon dioxide fire-extinguishing systems deliver CO_2 through piping systems with spray or "snow" nozzles. The high concentration of ex-

tinguishing agent required means that the compartment must be isolated by bulkheads in case of fire, so systems of this type are preferred for smaller spaces.

Their use is essentially restricted to combustible liquids and electrical equipment. Carbon dioxide does not penetrate to a great depth, and so there are problems in putting out solid (smoldering) fires by this method. CO_2 is useless against metal and carbon fires, because the high temperatures that may occur in such fires can break down CO_2 to carbon monoxide and oxygen, and the liberated oxygen can promote the development of the fire. Certain metals such as magnesium can reduce CO_2 to carbon, e.g.:

$$CO_2 + 2\,Mg \longrightarrow 2\,MgO + C$$

so these metals can continue to burn, even after CO_2 has displaced oxygen.

The toxicity of the extinguishing agent means that special measures must be taken for personnel safety (redundant warning systems). CO_2 fire-fighting installations are increasingly used for local protection, e.g., in laboratory fume hoods or computer centers.

Powder extinguishing systems can be used primarily as local protective devices for special applications, e.g., to extinguish compressed gases or organometallic liquids. This type of system has the advantage that its use is largely independent of temperature (−50 to +60 °C). Powder extinguishing agents are based on sodium hydrogen carbonate, potassium hydrogen carbonate, potassium sulfate, and other chemicals. Sodium chloride or potassium chloride powder can be used against metal fires.

Halon extinguishing systems can be used only with special approval because of current bans on these halogenated hydrocarbons; their application is limited to military uses, and on aircraft, spacecraft, and ships.

Semistationary, nonautomatic fire-extinguishing systems have recently come into increasing use alongside automatic systems. In such a device, the extinguishing agent is delivered through fixed piping from mobile supply units operated by the fire-fighting service. This kind of system is effective only when it is carefully matched to the fire service's equipment; it is used chiefly where the plant has its own fire-fighting unit. The same extinguishing media can be used as in automatic systems.

Dry or wet standpipes are almost always required because they markedly improve the performance of the fire-fighting service.

Fire-Fighting Methods. Industrial fire-fighting includes both the training of employees to carry out immediate response, and the installation of fire extinguishers or wall hydrants to deliver suitable extinguishing agents.

Establishing a properly trained in-plant fire-fighting service improves efficiency; training and equipment should be similar to those of the municipal fire services. Professional industrial fire-fighting services differ from in-plant services in that they are recognized by government agencies, and are trained, certified, and equipped to the same level as municipal fire departments. They represent the highest level of fire protection in industrial plants. Their value stems from local knowledge of the personnel, special equipment tailored to the plant, and the fact that they can work continually to provide high-quality fire-prevention and fire-protection services.

An essential aspect of industrial fire precautions is continuous firefighter training, together with combined exercises with plant personnel [145].

3.4.2. Explosion Prevention and Protection

3.4.2.1. Introduction

Flammable substances (gases, liquids, and solids), if in the form of gas, mist, or dust and mixed with a gaseous oxidizer (most commonly atmospheric oxygen, but other substances such as pure oxygen and chlorine can serve), can form an explosive mixture. The explosion of such systems is generally a fast, exothermic oxidation – a gas-phase chain reaction with chain branching [146]. Special aspects are presented by substances that are not only oxidizable in the gas phase, but can experience exothermic, explosive decomposition reactions without other reactants; examples are ethylene, ethylene oxide, and acetylene.

A gas-phase explosion is initiated by an ignition source, delivering sufficient energy and having a suitable energy distribution. The reaction initiated propagates spontaneously through

the mixture. Such combustion reactions are accompanied by the release of a large quantity of energy with increases in temperature and pressure (and often also by the formation of dangerous reaction products). The hazards associated with an explosion are thus governed by three factors :

Occurrence of an explosive mixture
Presence of an effective ignition source
Effects of an explosion

These factors provide a logical structure for explosion prevention and protection in the following order:

Hazard identification
Risk assessment
Identification of countermeasures, risk reduction

3.4.2.2. Hazard Identification

(see also Sections 2.2.2, 2.2.3)

In gas-phase explosions, it is not the flammable material on its own that represents the potential hazard, but its contact or mixing with an oxidizer. The first step in identifying the hazard is therefore to define the combustion properties of the substances. The result indicates whether, and under what conditions, the substances can give rise to an explosive gas mixture. These conditions are characterized by data such as flashpoint, lower and upper explosion limits, and limiting oxygen concentration.

The second step is to determine the (minimum) requirements for the explosion hazard to be activated, i.e., the ignition characteristics of the system. These include the minimum ignition temperature for a dust layer, the ignition temperature of a flammable gas or liquid, the minimum ignition temperature of a dust cloud, and the minimum ignition energy.

The third step, focusing on the behavior of the explosive system after ignition, provides information on the expected physical explosion effects. Of interest are the heat of combustion, the explosion pressure, the rate of pressure rise, and the maximum experimental safe gap.

After the characteristics of the substances are known, this information has to be linked to the dimensions and parameters of the real chemical process and plant. Since substance data are obtained under standard laboratory conditions, it is important to know how they depend on factors such as temperature, pressure, volume, and volume of the process and plant under consideration. The basic transformation rules are qualitatively summarized in Table 11 [147].

It is necessary to compare substance properties with parameters of the chemical process and plant, not only for normal operating conditions, but also for failure states of the process and of the plant. Such analysis is particularly important for identification of process and plant conditions that may lead to the release of energy (i.e., creation of an ignition source) into the chemical system being handled (see the discussion of ignition hazards in Section 3.4.2.3).

3.4.2.3. Explosion Risk

The necessary condition for an explosion in the gas phase is the simultaneous occurrence of an explosive mixture and an effective ignition source. The likelihood of an explosion may therefore be considered as the product of the probability of the occurrence of an explosive mixture and the probability of the presence of an effective ignition source. The risk is defined as the combination of the (relative) frequency of an event occurring and the expected extent of damage; this means that explosion effects must also be considered.

Likelihood of Explosive Mixtures. Even when the chemical and physical relationships are understood in detail and years of practical experience have been accumulated, the likelihood that explosive mixtures may arise cannot be quantitatively evaluated, and it is doubtful whether such an evaluation would be of any use. It is more to the point to define a few qualitative categories that take in the limiting cases. In these categories, the probability of the formation or presence of a hazardous explosive mixture is described verbally [148]. The following zone definitions have been worked out in the course of European harmonization of explosion prevention and protection regulations [149]:

1) The explosive atmosphere (i.e., mixture under normal conditions) is present continuously, for an extended time, or frequently

Table 11. Transformation rules

Substance characteristics ∗	Real plant parameters			
	Temperature	Pressure	Dispersion	Volume
T_f (flashpoint)		+		
LEL (lower explosion limit)	−	−	−	0
UEL (upper explosion limit)	+	+	(+)	0
LOC (limiting oxidator concentration)	−	−	−	0
MIT (minimum ignition temperature)		−	−	−
MIE (minimum ignition energy)	−	−	−	0
p_{max} (maximum explosion pressure)	−	+	0	0
$(dp/dt)_{max}$ (maximum rate of explosion pressure rise)	+	+	+	−
MESG (maximum experimental safe gap)	−	−	(−)	(0)

∗ Laboratory data
+, −, 0 indicate parallel, inverse, or neutral effects; i.e., increase in value of parameter results in increase, decrease, or no change in substance property compared with laboratory data.

(i.e., for most of the time in the process under consideration). This zone is, as a rule, limited to the interior of apparatus: Zone 0 for flammable gases, vapors, and mists; Zone 20 for flammable dusts.

2) The explosive atmosphere may be present occasionally during normal operation: Zone 1 for flammable gases, vapors, and mists; Zone 21 for flammable dusts.
3) The explosive atmosphere is present only rarely and for a short time only (e.g., in the case of an infrequent malfunction or upset): Zone 2 for flammable gases, vapors and mists; Zone 22 for flammable dusts. (Zone 22 also covers deposits of dust that can lead to an explosive atmosphere in the infrequent event of the dust becoming agitated in air.)
4) The "zone-free area" where the occurrence of explosive mixtures is not anticipated, even in infrequent upsets (nonhazardous area).

In countries whose codes are based on United States practice, the classification differs slightly, but the rating arrived at is similar [150].

A mixture of flammable substances with air is explosive only if the concentration of flammable substances lies between the lower and upper explosion limits (see Sections 2.2.2 and 2.2.3 for definitions). With flammable liquids, if the processing temperature is above the flashpoint, an explosive mixture can be produced above the free liquid surface. If a flammable liquid is atomized (to form a mist or aerosol), the degree of dispersion can be sufficient to generate an explosion hazard, even at temperatures below the lower explosion point. The probability of occurrence of explosive mixtures for a given process in a given plant is not constant for all points in the system:

1) Inside the apparatus, this likelihood depends on the substances present, the prevailing process conditions, and the possibility of upsets
2) Flammable gases, vapors, liquids, or dusts can enter the outside atmosphere at openings and leaks (release points) and form explosive mixtures with air (explosive atmosphere)

The frequency of a release in the vicinity of apparatus depends on the procedures used; it is important to retain flammable substances in closed vessels, not just on grounds of explosion prevention, but also for reasons of exposure and environmental protection. Accordingly, portions of the plant containing flammable substances, as well as equipment and piping associated with these plant sections, are designed to be technically tight in relation to the mechanical, chemical, and thermal stresses anticipated under the intended operating conditions. The following examples illustrate the differences between various forms of release [151]:

– Continuous sources (continuous release) include the permanent free surface of a flammable liquid, open to the atmosphere (open vessel or separator, immersion bath, conveyor belts carrying products moist with solvent) at or above the flashpoint.
– Primary sources (occasional release) include expected leaks from flanges, shaft seals, apparatus and connections opened in normal

operation, venting to the atmosphere during filling or as a result of overpressure, occasional upsets such as the failure of an unmonitored cooling system, sampling, and drainage.
– Secondary sources (infrequent release) include cracks in apparatus walls or piping, defective gaskets in flange joints, defective shaft seals, and emergency pressure-relief devices (e.g., safety valves).

Dilution in the air causes the concentration of flammable substances to decline with distance from the release point. The size of an explosion hazard region thus depends on the rate of release and the propagation conditions. The rate of release depends in turn on the geometry of the source and the substance and process parameters, all of which control the mechanism of release (gas release, flash evaporation, spray jet, pond evaporation).

A central problem is to determine the maximum anticipated leak rate [151]. Catastrophic leaks, e.g., a large leak in a pipe or complete pipe rupture, do not fall within the scope of current explosion regulations.

Figure 43. Hypothetical extent of an explosive cloud as a function of release rate of flammable substances for different ventilation conditions
Enclosed areas: normal, $C/f = 5$; unfavorable, $C/f = 0.2$
Open-air situation: normal, $C/f = 100$; unfavorable, $C/f = 4$
Extent $= 2r_z$ (see Fig. 44 for definitions); assumed typical LEL ca. 50 g/m^3

Other expected malfunctions generally lead to leaks up to ca. 0.01 – 1 kg/h. The failure of a seal (leak size in the mm^2 range) results in a release rate up to ca. 10 kg/h for gases or 100 kg/h for liquids, but in liquids it may be that only a fraction of this amount contributes to the explosion hazard.

The main factors governing propagation of released substances are the density of the fluid, the momentum of the release, and the climatic conditions and topography of the surroundings (see Section 1.4.2).

Ventilation conditions can contribute greatly to reducing explosion hazards:

– *Local ventilation.* If the atmosphere is exhausted from the release point (e.g., around the margins of open vessels), flammable substances can be kept from spreading into the compartment.
– *Dilution.* The concentration of flammable substances is lowered by dilution in air so that the concentration may fall below the lower explosion limit.

Figure 44. Ventilation model
V_0 volume considered; $\dot{G}_{\max}$ release rate of flammables (mass/time); $\dot{V}_0$ fresh airflow (volume/time); $C = \dot{V}_0/V_0$ air change (1/time); f ventilation quality factor (1 – 5); $V_z = f\dot{V}_{\min}/C$ hypothetical residual sphere of explosive mixture with radius r_z on dilution by fresh airflow; $\dot{V}_{\min} = \dot{G}_{\max}/k \cdot \mathrm{LEL}$ required minimum fresh airflow to dilute below LEL with safety factor k

In buildings above ground with no special air intake or exhaust openings, an airflow of at least 1 h^{-1} is normally maintained. In typical chemical plants with natural ventilation, the temperature differences commonly present between different process apparatus units produce an airflow $> 3\,\mathrm{h}^{-1}$. Below ground, ventilation conditions are generally less favorable; most flammable substances are denser than air, so they tend

to collect in places such as drains or underfloor spaces.

Artificial ventilation moves larger amounts of air, increasing dilution. Air movement can be designed in an artificial ventilation system, with allowance for explosive mixtures with density different from that of air. In an outdoor installation, air movement produces a much more rapid turnover.

Figure 43, based on a simple ventilation model (Fig. 44) [148], [151], shows the characteristic size of an explosive cloud as a function of release rate for various airflows. For a given release rate, an explosive cloud in a closed building is a factor of 3 – 6 larger than in an outdoor plant.

Initially, a hazardous area is created around any potential release source. Figure 45 shows the size of the hazardous areas around a stirred tank opened for charging in a ventilated room. The areas where an explosion hazard exists are identified in the ground plan. Where these areas overlap, the zone of higher probability prevails. For clarity, the hazardous areas have been smoothed to simple geometric forms containing the actual regions. The result is an area classification document. Figure 46 shows such a document for a simplified facility in a compartment with artificial ventilation. In practice, especially in smaller compartments, it is normal to extend, say, Zone 2 out to the boundaries of the room [151], [152].

Figure 45. Type, shape, and extent of hazardous areas for a stirred vessel opened during normal operation [151]

Ignition Hazards. In view of the various ways energy can be introduced into an explosive system, 13 types of ignition sources have been defined [148]:

Hot surfaces
Flames, hot gases
Mechanical sparks
Electrical installations
Transient currents
Lightning
Static electricity
Electromagnetic waves (high frequency)
Electromagnetic waves ($3\times10^{11} - 3\times10^{15}$ Hz)
Ionizing radiation
Ultrasonics
Adiabatic compression, shock waves
Chemical reactions

The conditions for such ignition sources to become effective can be generalized in only a few cases. The effectiveness of ignition sources involved in process operation or the working of apparatus depends strongly on the properties of the substances present (see Section 3.4.2.2).

Hot surfaces may be present in normal operation (heated piping) or may arise through malfunctions (increased friction between moving parts). A large hot surface can initiate an explosion if its temperature exceeds the ignition temperature of the fuel that is present. With regard to small (cm^2 scale) hot surfaces, studies have shown that these must be at temperatures much higher than the ignition temperature before they can initiate an explosion [153].

Flames and hot gases are among the most effective ignition sources.

Visible sparks produced mechanically (friction, impact, and grinding) can be attributed to the combustion of metal particles heated to 1000 °C on separation from solid materials. The effectiveness of such sparks as ignition sources depends on the material as well as the ignition temperature of the fuel. For most optimal mixtures of common flammable gases and vapors with air, sparks from friction against steel are effective ignition sources; however, these sparks are effective on dust – air mixtures only if the minimum ignition energy and ignition temperature are low. At relative speeds of ca. 1 m/s, visible frictional sparks no longer occur (Fig. 47). Impact sparks may be effective especially with the combination of light metal and non-stainless steel.

Figure 46. Plan view of the area classification of an in-house chemical plant
Zone 1 enclosed by boundary; Zone 2 by boundary.

Figure 47. Generation of mechanical sparks
Typical curve for steel construction material [153]

Electrical sparks and hot surfaces may occur as ignition sources in electrical installations. Explosive mixtures can be ignited, even at low voltages. Electrical equipment is considered a priori safe if none of the following values is exceeded: voltage 1.2 V, current 0.1 A, energy 20 μJ, power 25 mW. The use of electrical devices in hazardous areas is strictly (and internationally) regulated (Fig. 48), and as a rule such equipment is rated on the basis of type approval tests or comparable technical documentation, e.g., a manufacturer's certificate [155].

Static electricity as an ignition source is a typical example of how a realistic assessment demands an analysis of the interaction of substance properties and process/plant parameters [156], [157]. Electrostatic discharges occur primarily with substances of very low electrical conductivity; discharges result from fast separation processes at interfaces. Solids with surface resistances $< 10^9\ \Omega$ and liquids with conductivities $> 10^8$ S/m cannot be charged to dangerously high potentials, provided they are grounded. In the case of a liquid capable of holding a charge, charging (e.g., in stirring) can be significantly increased if the liquid is a multiphase system. Dusts often acquire an electrostatic charge during handling. Gases do not become charged, but solid or liquid contaminants or solid or liquid species formed by condensation in flowing gases can lead to an electrostatic charge.

If, say, a pipe wall is sufficiently highly charged, the dielectric strength of the ambient air is exceeded and a gas discharge ensues. The effectiveness of the discharge as an ignition source depends on the form of the discharge as well as the sensitivity of the explosive mixture.

Figure 48. Explosion-proof electrical equipment, tested and certified, with the required explosion-resistant marking and data of testing house (with kind permission of the manufacturers STAHL and ABB CEAG)
A) Limit switch, flame-resistant enclosure "d", suitable for use in zone 1, explosion hazard due to products of Group II C and Temperature Class T6 (e.g., CS_2);
B) Electronic device for PCI, intrinsic safety "i(a)", suitable for use even with zone 0, explosion hazard due to products of Group II C and Temperature Class T 6

Spark discharges take place when charged, conductive objects are brought close together and a discharge channel forms between these "electrodes." Such discharges are effective ignition sources if the energy stored capacitively is greater than the minimum ignition energy of the mixture, as is commonly the case with large objects. Conductive substances (resistivity

$< 10^4\ \Omega \cdot \mathrm{m}$), if isolated, represent an increased ignition hazard.

Brush discharges can occur from charged nonconductive substances. The counterelectrode can be a conductive, grounded piece of equipment or a (grounded) person. The effectiveness of bruhs discharges as ignition sources depends on the charged area; they can ignite gaseous mixtures with a minimum ignition energy of up to ca. 3 mJ (dust – air mixtures cannot generally be ignited by brush discharges).

At pointed electrodes, brush discharges give way to corona discharges; this weakest form of discharge, in its pure form, is not usually an effective ignition source.

If a grounded, conductive body has a thin, chargeable coating, charge can be drained off, and the danger of ignition by brush discharge may be greatly reduced. If rapid charging takes place, as in the pneumatic conveying of dusts, the charge density in the coating can become so high that propagating brush discharges with high energy content can occur (Fig. 49).

Figure 49. Propagating brush discharge from a chargeable surface [154]

Chemical reactions, by producing heat, can raise the temperature of any substances present, and thus become ignition sources. In highly reactive systems, this can happen through spontaneous exothermic reactions; such systems are said to be auto-igniting or unstable. Self-heating does not occur in less reactive systems under normal operating conditions. If heat removal is blocked, e.g., by (oxidation-sensitive) solid deposits, the temperature can rise to the point that the conditions for ignition are attained.

Other conceivable types of ignition source are less important in practice and cannot be discussed here.

Ignition sources can be categorized in a similar way to explosion hazards (the rating of explosion prevention measures is discussed later in this section).

Explosion Effects. Structures that may rupture in an explosion present a danger to the surroundings, owing to overpressure, underpressure, flames, and expelled fragments. In the field of explosion protection, design data for apparatus are compared with the anticipated maximum explosion pressure. If the possible explosion effects exceed the design limits of the apparatus, and product releases or flying debris from ruptured equipment cannot be ruled out, substantial consequences have to be reckoned with. In general, severe effects will not extend beyond a few tens of meters (see Section 1.4.3).

Rating of Explosion Prevention Measures. In the chemical industry, a distinction is made between cases involving appreciable impacts (i.e., severe personal injury or environmental harm) and those where damage to plant and equipment is the most that can be expected. If no appreciable impacts are anticipated, then economic considerations alone (plant availability, product loss, damage) dictate that an analysis be done to determine how tolerable is the occurrence probability of an explosion. If appreciable impacts cannot be eliminated, the occurrence probability of events must be made low enough that such events are regarded as positively prevented. The following commonly accepted rating system should be applied to such cases:

A) Where an explosive atmosphere is anticipated most of the time (Zone 0 or Zone 20), the occurrence of an ignition source is never tolerable, not even under extreme fault conditions.

B) Where an explosive atmosphere occurs occasionally (Zone 1 or Zone 21) the only ignition sources that are tolerable are those that result from a very infrequent malfunction, e.g., during run-up of a mill rotor (mechanical sparks) or a short- circuit (electrical sparks).
C) Where an explosive atmosphere can occur only infrequently (Zone 2 or Zone 22) continuous ignition sources or those present for long periods or for most of the time, cannot be tolerated. Sources occurring only as a result of a (simple) upset, e.g., a hot surface due to abnormal overheating of a heat exchanger, can be tolerated.
D) In an area where an explosive atmosphere cannot occur at any time, even under extreme upset conditions (i.e., nonhazardous area), the question of possible ignition sources is irrelevant. Even continuous ignition sources remain ineffective, and can be tolerated (e.g., the flame in an off-gas flare system).

For these four categories, Table 12 uses keywords to summarize complementary measures to restrict the formation of explosive mixtures and to avoid ignition sources.

The prerequisite for such a rating (categories B and C) is that the occurrence of an explosive atmosphere and the occurrence of an ignition source are mutually independent; i.e., both do not result from a common malfunction in the process or plant (common mode failure).

The explosion rating of a system states what zone exists for the situation under consideration, and in what zone the ignition sources found would still be tolerable. This safety balance can take different forms, depending on the specific question posed:

1) The ignition source appears to be tolerable in the ascertained category of occurrence of explosive mixtures. The system properties are so favorable that the probability of occurrence of an explosion is sufficiently low. Such a system is said to be intrinsically safe. No further precautions are necessary [158].
2) There is a gap between the category in which the ignition source would still be tolerable and the ascertained zone. Precautions are necessary, but they need only complement the existing intrinsic safety. Three cases can be observed:
   a) For a reduction by one level (e.g., explosion hazard lowered from Zone 0 to Zone 1), a "simple" measure is sufficient
   b) For reduction by two levels (e.g., from Zone 0 to Zone 2), the measure must satisfy extensive requirements
   c) For a three-level reduction (e.g., from Zone 0 to "zone-free"), the reliability of the measure(s) taken must be enhanced even more, e.g., by redundancy

3.4.2.4. Explosion Risk Reduction

There are two options for lowering the explosion risk: measures to prevent an explosion, or measures to limit its effects.

If explosion prevention is chosen, measures are instituted to reduce the explosion hazard (preferable) or the ignition hazard; combinations of both approaches are possible. Limitation of the explosion hazard establishes a zone. If the limitation of the ignition danger meets the requirements for this zone, prevention of an explosion is insured.

Reduction of Explosion Hazard. The avoidance or restriction of explosive mixtures should always be the first priority. Especially outside closed systems, this rule also applies on grounds of occupational safety and health, as well as environmental protection. A simple way is to replace flammable substances with nonflammable ones (e.g., a flammable solvent by water).

Inside apparatus and equipment, the formation of explosive mixtures can be prevented by:

1) Keeping the concentrations of flammable substances in the gas phase outside the explosion range. Gas systems can be operated at overpressure, to prevent entry of air. Suitable purging is needed when such a system is placed in service [159]. In waste-gas streams, the total concentration of flammable components can be held above the upper explosive limit, e.g., by adding flammable gases (enrichment). Conversely, a stream can be diluted with air to reduce the concentration of flammable gases below the lower explosion limit. With liquids, the formation of

Table 12. Keywords for explosion risk assessment

Category	Occurrence of explosive mixtures	Keyword	Tolerance of ignition sources	Keyword
A	continuously/for long periods/frequently	permanently	not even in very rare situations	never
B	occasionally in normal operation	occasionally	not even in rare situations	rarely
C	in rare situations and with short duration	rarely	not in normal operation	occasionally
D	not even in very rare situations	never	in normal operation	permanently

explosive mixtures can be avoided by keeping the temperature sufficiently far below the flashpoint. Substances with low flashpoints can often be replaced by substances whose flashpoints are a safe margin above the ambient and process temperatures.

2) Displacing or replacing air (or other gaseous oxidizing agent) with an inert gas until the oxidizer concentration drops below a case-specific critical level (see Section 2.2.2). A dryer for flammable dusts can be operated with combustion off-gases no longer having oxidizing properties, or a solvent tank can be purged with nitrogen.

In the vicinity of process equipment, the occurrence of explosive mixtures can be largely controlled by:

- Using closed systems to avoid release of flammable substances during normal operation. Examples include gas equilization lines for storage tanks, and the use of lock systems for tank filling and emptying.
- Installing apparatus that has more integrity in terms of possible leaks. Examples include: welded piping to avoid flange joints; O-ring seals instead of stuffing boxes; and materials less susceptible to fracture, such as metal instead of glass.
- "Good housekeeping," i.e., the immediate removal of all flammable liquids and dusts released in the vicinity of plant equipment.
- Creating suitable ventilation to insure the instant dilution of any gas mixtures. This practice can be established throughout the plant (e.g., open-air plant). Selective efforts can also be made to avoid formation of explosive mixtures in areas where sparks can occur, e.g., the installation of an open cage on stirrers and pumps insures that vapors escaping at the shaft seal are immediately diluted with air.

Reduction of Ignition Hazard. The ignition hazard from each type of ignition source listed in Section 3.4.2.3 can be reduced by specific practices. Hot surfaces can be avoided by matching the cooling capacity to the energy dissipated in the apparatus, and providing overtemperature protection. If necessary, insulation can be installed as a form of shielding.

Possible ignition sources involving frictional heat or sparks can be dealt with by suitable design:

- Use of adequately sized components with sufficiently long service lives
- Avoidance of improper material combinations, use of materials with favorable dry friction properties
- Monitoring of temperatures, and of lubrication and cooling systems
- Maintenance of adequate clearance between moving parts

Electrical ignition sources can be avoided by limiting electrical characteristics such as energy and power so as not to produce sparks capable of initiating an explosion ("intrinsic" safety, as in instrumentation circuits) or by preventing extreme conditions and overload in equipment that is free of ignition sources under normal conditions ("enhanced" safety, as in electric power distribution and lighting).

The chief way of reducing ignition hazards due to electrostatic discharges is to use (grounded) conductive construction materials, and to ground conductive objects, liquids, and personal (resistance to ground $< 10^6\ \Omega$). The use of objects made of chargeable, nonconductive substances is generally permitted in Zone 2, but not in Zones 0 and 1. Ignition hazards can be avoided by limiting the dimensions of such objects, depending on the zone, and the ignition sensitivity of substances present; e.g., chargeable surfaces can be kept below $100\,\mathrm{cm}^2$ for substances classified in explosion groups II A and II B in Zone 1. Similarly, the thickness of

chargeable coatings on conductive substrates can be restricted (e.g., < 2 mm for substances belonging to explosion groups II A and II B) and ignition thus avoided.

When working with chargeable liquids, dangerous charging can be avoided by limitations on filling rates (e.g., < 7 m/s for hydrocarbons in a pipe with nominal diameter 50 mm) and by systematic under-level filling.

Ignition hazards due to chemical reactions are avoided by excluding pyrophoric systems from hazardous areas, and maintaining safe process conditions (e.g., layer thickness, temperature, residence time, and thermal load in drying processes).

Limitation of Explosion Effects. Design practices can insure that, if an explosion does take place in an apparatus, it does not have appreciable impacts. Maximum possible pressures generated by an explosion can be determined to acceptable accuracy by thermodynamic calculations, or measured experimentally.

Explosion-pressure resistant design consists in designing apparatus to withstand the anticipated explosion pressure, generally less than 10 times the initial pressure for fuel – air mixtures. If the safety factor relative to yield strength is smaller, the term used is explosion pressure shock resistant design. In piping where detonations are possible, the standard design for PN 10 includes significant hidden reserves that are adequate for nominal diameters ≤ 200 mm; for nominal diameters > 200 mm, the piping should be designed to PN 16 at least. In interconnected vessels, an explosion in one portion can raise the pressure in the remainder; in this way, a (consequent) explosion can be induced, with a higher initial pressure. Explosion protection in such a case may entail decoupling of volumes.

Pressure-relief devices (rupture disks or explosion valves) open as the explosion pressure rises and reaches their response pressure. They insure that the apparatus experiences only a reduced explosion pressure. Such systems are designed especially for protection against dust explosions, where the rate of pressure rise is generally fairly low [160], [153]. Naturally, pressure relief must not create new hazards (see Section 3.5.1).

In an explosion suppression system, a complex of detectors respond at a very early stage in the explosion, and an extinguishing agent (e.g., ammonium-phosphate-based powder) is injected on a scale of milliseconds in order to quench the explosion. The protected apparatus can then be designed for a lower pressure, e.g., 200 kPa. The amount of extinguishing agent needed depends on the violence with which the substance explodes, and the volume of apparatus to be protected (typically 50 kg per 25 m^3 for St 1 dusts; see also Section 2.2.3).

Isolation ("decoupling") in the context of explosion protection means separation of an explosion-resistant section (where an explosion can take place without danger) and a non-explosion-resistant section (where explosions must be positively prevented). A number of devices have been created to prevent flame-front breakthrough; these employ several principles:

- Fast mechanical closure and lock-type features
- Extinguishing of flames in narrow gaps
- Use of flame-extinguishing agents (as in explosion suppression)
- Flame arresting by high counterflow velocity
- Flame arresting by liquid barriers

Equipment selection must take into account substance properties; key aspects include sensitivity to ignition and propagation velocity (see Section 3.5.3). Narrow gaps are also employed in the design of explosion-proof equipment, e.g., fans, gas pumps for recycle systems, submerged pumps, and internal combustion engines [161]. This principle, when used in electrical equipment design, results in the rating "flame-proof enclosure."

3.4.2.5. Legal Aspects

In the domain of European legislation, EU directives set the framework for explosion protection at continental and national levels. The principal directives are ATEX 100 a [162], ATEX 118 a [163] and portions of the Machinery Directive [164].

The ATEX 100 a directive, aimed at manufacturers of "devices and protective systems intended for use in explosion hazard regions," governs the quality and certification of such devices and systems. (For electrical equipment intended

for use in Zones 0 and 1, type testing and a certificate of conformity issued by an authorized agency have long been required [165], according to earlier harmonized European standards.) For Zone 2 equipment, the manufacturer's declaration of conformity is sufficient. Similar rules apply for equipment to be used in areas where there is a dust explosion hazard (this equipment is still classified according to earlier zone definitions with just two types, i.e., Zone 10 and Zone 11, substantially comparable to the "new" zones 20 and 21 or zone 22, respectively).

The ATEX 100 a directive, in contrast to its predecessor, now includes equipment and devices as well as protective systems "which are intended to halt incipient explosions immediately and/or to limit the effective range of explosion flames and explosion pressures," and makes such equipment and systems subject to certification. The pertinent standards are being drawn up or are under revision by the European standards institutions CEN (e.g., committees TC 305 and TC 114) and CENELEC (e.g., TC 31), partly in collaboration with international standards bodies such as ISO and IEC.

The ATEX 118 a directive (in preparation) applies to "the minimum requirements for improving the safety and health protection of workers potentially at risk from explosive atmospheres." It is aimed at plant and process operation and represents a synthesis of earlier national regulations, reflecting the basic principles of explosion protection.

3.4.3. Safety Techniques Based on Process Control

Safety objectives in chemical process plants can be achieved with systems based on process engineering and process control engineering (PCE). Technical or organizational measures, or a combination, can be employed. Alternative solutions that are equivalent from the safety standpoint can be found, so that the most appropriate solution from the process engineering standpoint can be selected.

Safety concepts for specific safety objectives set down in technical regulations must take first priority.

This section deals with PCE equipment for safety in process plants. The discussion is based on NAMUR Recommendation NE 31 [166], VDI/VDE 2180 [167], and provisional standard DIN V 19250 [168], with some points from the book *Praxis der Sicherheitstechnik* (Practical Safety Engineering), vol. 1, *Anlagensicherung mit Mitteln der PLT-Technik* (Safety Techniques Based on Process Control Engineering) [169].

The PCE safety measures suggested in this section are tailored to the risk component that would arise from a process plant in the absence of such measures. This way of assessing risks is only qualitative, and must be carried out by case. Other procedures leading to a comparable safety level are possible.

As used in this section, "safety objective" refers to preventing injuries to persons, major environmental damage, and major equipment damage to property. Safety precautions for electrical installations and equipment, occupational safety practices, or measures taken to safeguard machinery are excluded.

3.4.3.1. Integration of PCE into the Safety Concept

As a rule, safety requirements under DIN V 19250 and the measures required are more stringent the greater the risk that must be covered. The risk must be reduced at least to the acceptable limit (DIN VDE 31000 [170]; see Section 1.3) by non-PCE or PCE safety measures. Non-PCE safety measures and equipment may include elimination of ignition sources, isolation to control explosions, pressure-proof design, safety valves, interception spaces, and retention systems.

PCE safety measures commonly reduce only a portion of the risk resulting from a unit. The risk on which the following discussion is based is just the portion to be covered by PCE safety measures. The remainder can be dealt with by non-PCE safety measures.

Safety tasks allotted to PCE vary widely in character and significance. Similarly diverse are the safety requirements on PCE equipment and practice (technical; nontechnical, e.g., organizational).

The use of PCE equipment for plant safety, the tasks assigned, and their performance are among the matters to be decided in a general

safety review. The following are determined in the safety conference:

- The safety objectives (personnel, environment, property)
- The PCE equipment to be used for plant safety
- The classification of PCE equipment by task:
  - Operating systems
  - Monitoring systems
  - Safety systems
  - Damage minimizing systems
- The required technical and organizational measures (e.g., cycle of functional testing)

The safety review is the basis for the task-driven planning, construction, and operation of PCE safety systems, at a reasonable expense and with clearly defined functional scope.

The selection of measures for maximum simplicity and direct impact generally leads to a safe and economic solution. PCE safety measures find use when other approaches are not applicable, inadequate, or uneconomic, given a comparable level of risk reduction. The economic comparison takes in not only one-time investment costs, but also recurring maintenance expenses.

The requirements for PCE safety and monitoring systems are derived from this definition. Inadvertent triggering of the PCE safety and monitoring systems during any phase of the process must not lead to an unacceptable fault condition of the plant.

3.4.3.2. Classification of PCE Systems

In chemical process plants, PCE systems are classified as operating systems, monitoring systems, and safety systems (Fig. 50), in relation to the ranges of a process variable:

- Specified operation, subdivided into
  - Normal operating range
  - Admissible error range
- Nonspecified operation – nonadmissible error range

Region 1 of Figure 50 corresponds to the situation in which factors inherent in the process keep the process variable from reaching the nonadmissible error range. A monitoring system is sufficient. The process variable is brought into the normal operating range by automatic or (after a status signal) manual action. Region 2 represents the case where the process variable exceeds the limit for the nonpermissible range. Because another protective device is present (safety valve, rupture disk, rapid-opening or rapid- closing valve), a PCE device connected ahead of it to signal or limit the increase in the process variable is classified under monitoring system. In region 3, the PCE device keeps the process variable from entering the nonpermissible range, and is therefore classed as a safety system.

PCE Operating System. PCE operating systems are used in specified operation of the plant in its normal operating range. These devices implement the automation functions required for production: measurement and control of all variables relevant to operation, including related functions such as logging and report generation. High-level control algorithms, complex control sequences, automated recipe processing, and optimization strategies are increasingly employed. Many binary, digital, and analog signals have to be processed if all these tasks are to be performed. Because the functions of PCE operating systems are called on continuously or frequently in operation, these devices are subject to plausibility checking by plant personnel, so that failures and malfunctions can be detected immediately.

PCE Monitoring System. When the plant is in specified operation, PCE monitoring systems responds to conditions in which one or more process variables are outside the normal operating range, but there is no safety reason to discontinue operation; i.e., these monitoring devices respond at the boundary between normal operating and admissible error ranges of process variables.

Acceptable fault conditions of the plant are reported, in order to evoke heightened awareness or direct action by operating personnel; the monitoring system may even initiate action itself to bring process variables back into the normal operating range.

Also included are PCE devices connected ahead of PCE or non-PCE safety systems in order, if possible, to prevent them from responding.

Figure 50. Functions of PCE systems

PCE Safety Systems. In contrast to the functions of PCE operating and monitoring systems, PCE safety devices have the function of preventing nonadmissible error state of the plant.

A PCE safety system is necessary if its absence would allow the plant to reach states that could lead directly to personal injury, major environmental damage, or major equipment damage.

The task of a PCE safety system is usually to monitor a process safety variable and take one of the following actions if the variable goes outside the admissible error range:

1) Initiate a control process
2) Notify the operating personnel (who are always present) so that the proper action can be initiated ahead of time

The functions of PCE safety systems always take priority over those of PCE operating and monitoring systems, and must be executed at a level near the process level with minimum complexity.

The functions of PCE safety systems, in contrast to those of PCE operating equipment, are called on extremely seldom, because the probability of occurrence of the undesired event is low, and because PCE operating, monitoring, and safety systems are often in a staggered configuration (Fig. 50).

Because they are called on so infrequently, it may be desirable to allow sharing of PCE safety components, such as actuators, by PCE operating systems, to enhance availability and facilitate plausibility checking. Such common components must meet the requirements for PCE safety equipment.

PCE safety systems employed for prevention of major equipment damage are designed solely on economic grounds and are not discussed here.

PCE Damage Minimizing Systems. PCE damage minimizing systems come into action: when the plant is in nonspecified operation; when an undesired event occurs. They limit the impacts on persons and the environment, limiting the extent of harm under these extremely rare circumstances.

If PCE equipment is used to detect the undesired event, what is monitored is not a process variable (e.g., pressure, temperature), but some other quantity such as the concentration of gases released in the atmosphere. Effectors put into action do not influence the process, but have to do with the threatened region outside the vessels, apparatus, and piping (e.g., initiation of a water curtain to prevent the spread of ammonia). PCE damage control devices are often combined with non-PCE damage minimizing devices and organizational measures.

3.4.3.3. Requirements for PCE Equipment for Process Plant Safety and Design Principles

PCE Monitoring Systems. No special requirements apply to PCE monitoring devices; they are treated like operating equipment.

PCE Safety Systems. If the interdisciplinary safety review establishes the need to employ a PCE safety system, the following procedure is employed [168]:

1) Qualitative estimation of risk
2) Setting requirements for PCE safety system
3) Definition of technical and organizational measures

In particular, the following steps are identified and documented:

- Task statement, safety problem
- Function of PCE safety system
- Technical design (principle)
- Nature and frequency of scheduled function testing
- Other organizational measures (e.g., scheduled maintenance; see Section 4.4)

Two points must be considered in the selection of PCE safety devices: the minimum risk reduction aimed for; and the safety-related availability of PCE safety systems.

Fundamental Requirement. PCE safety systems must be designed and operated in such a way that if one passive fault occurs, the protective function is still performed.

In the design of PCE safety systems, the safety-relevant availability must therefore be chosen such that the risk is reduced to a residual level lower than the limiting risk, even if one passive fault occurs.

The safety-relevant availability of PCE safety systems depends on:

- The failure rate due to passive faults
- The mean time to detect and remedy passive faults
- The degree of redundancy of the PCE safety system

The safety-relevant availability can thus be enhanced by the following practices, or a combination of them:

- Redundancy: the presence of more operable technical means than are required to fulfill the intended basic functions (e.g., special safety or reliability requirements)
- Homogeneous redundancy: redundant design of a device or parts thereof such that the redundant channels are identically structured, and operate by identical physical processes
- Heterogeneous redundancy or diversity: redundant design of a device or parts thereof such that the redundant channels operate by different physical processes or are differently structured
- Fail-safe quality: ability of a safety device to hold a process safety variable in a safe state, or to modify the variable directly into another safe state, on the occurrence of certain faults in the safety device
- Self-monitoring: a protective device is self-monitoring if, aside from certain faults, it is so constructed that all other faults are detected by the self-monitoring, and thus the safe state is achieved

To meet the requirements on PCE safety systems after risk estimation, distinction is made between high and low risk application [166].

Low Risk Application

Requirement: One passive fault must be detected and remedied within a time interval in which no violation of specified operation is anticipated.

Response: Single-channel PCE safety device with:

1) Short fault-detection time (e.g., high frequency of function testing, continuous plausibility checking); or
2) Low probability of passive faults of the PCE safety device.

A reduced risk may be present if non-PCE safety measures of a technical or organizational nature are employed.

High Risk Application

Requirement: One passive fault must not impair the ability of the PCE safety device to carry out the safety function. Independently of the process behavior, such a fault must be detected and remedied within a time interval in which the simultaneous occurrence of a second, independent fault is not anticipated.

Response: Redundancy of PCE safety device. In general, one-out of-two or (for simultaneously high production availability) two-out of-three design combined with regular functional checking is sufficient. Diversity (e.g., in acquisition of measurements) does not automatically enhance safety over homogeneous redundancy. It is a supplementary measure for preventing possible systematic faults.

Fail-safe or self-monitoring systems are equivalent to redundant devices.

Within a PCE safety system, combinations of these measures are possible depending on the particular availability requirements; e.g., acquisition of measured values may be redundant, control fail-safe, and actuator single- channel.

There are several ways to estimate risk. Quantitative evaluation is not possible for the chemical production plants under consideration here (see also Sections 1.3 and 3.3), because the wide variety of processes and the comparatively short lives of plants mean that adequate statistical material cannot be obtained. This holds equally for the safety relevant availability of PCE safety devices.

Accordingly, the qualitative scheme of Table 13 is used in the design of PCE safety systems. It involves measurements of the risk to be dealt with as well as the safety-relevant availability of the PCE safety systems (the availability of the single- channel device when there is redundancy).

Table 13. Grading of PCE safety systems by risk level and safety-related availability of PCE safety system (availability of single-channel device when there is redundancy)

Safety availability	Risk to be covered	
	Lower	Higher
Higher	I	II
Lower	II	II

Damage Minimizing Systems. Because the undesired event is expected to occur extremely seldom, damage minimizing systems are commonly single- channel units, and must be tested for function in regular intervals.

Principles for Design and Construction of PCE Safety Systems. A number of important principles must be considered in the design and construction of PCE safety systems:

- Proven, reliable hardware and installation methods must be employed.
- The PCE safety device must be simple in construction. Fault effects (e.g., secondary or sequential faults in the PCE safety device) should, if possible, be limited by suitable barriers to fault propagation: high-impedance decoupling, short- circuit strength, galvanic isolation, etc.
- Harmful effects due to environment and products, e.g., vibration, impact, static strain forces, thermal action, corrosion, contamination, wear, and electromagnetic effects (including those resulting from lightning, ripple content in power supply, grid malfunctions, grid noise, etc.), must be taken into account.
- Fail-safe properties of equipment must be utilized (actuator with spring return to safe position, closed circuit to reset, etc.).
- When operating and monitoring systems are shared with PCE safety systems: the safety function must take priority over other functions; and the shared elements must be rated as for the safety device.
- The measurement of process safety variables, processing operations, and the implementation of the safety function must be done with accuracy and speed suited to the safety problem.
- The measurement ranges of process safety variables must be chosen so as to insure adequate resolution. Limiting values must be far enough from range end points so that resolution is still guaranteed if measurement errors are within tolerance.
- The correct setting of limiting values must be protected against inadvertent change.
- As a rule, automatic reactivation after initiation of the safety function should be disabled.
- Whenever possible, process safety variables should be selected such that they can be measured directly, simply, and by a proven method. Indirect derivation of process safety variables by combining measurement signals should be employed only when direct measurement is impossible or unreliable.
- It is desirable to record process safety variables.
- Analog process safety variables should be displayed, together with the limiting values, in the monitoring (control) room, or at local

control panels. In this way, operating personnel can do plausibility checking, so that fault detection times are kept short and the limiting value setting can be checked easily.
- The design of PCE safety systems must also take account of maintenance and start-up needs. Ease of inspection and accessibility of all components of the PCE safety system are important, even in the planning phase.
- Manual overrides can be provided to allow inspection or repair of PCE safety systems during plant operation.
- In isolated cases, redundant PCE safety systems should be examined to determine whether fire hazard or the possibility of mechanical damage necessitates: a split construction; or a protected and/or separate power supply and spatial separation of cable runs for both channels.

Use of Programmable Electronic Systems (PES). Most PCE safety systems are hardwired. The main arguments for this are:

1) The setup must be simple and straightforward.
2) The PCE safety device is seldom, or never, modified while in service.
3) Only a few of the PCE devices in a process plant are safety devices.

In special cases (more complex protective devices), if the use of PES is more economic, the following principles apply:

1) Certified systems can be used for both single-channel and multichannel safety devices in the applications, and under the conditions, set forth in the test certificate.
2) Noncertified systems may be used for safety measures only as part of a multichannel safety device, and then for at most one channel. The other channels must be either hardwired (as required for PCE safety devices) or constructed with certified systems. The following minimum requirements apply to the noncertified system:
   - The system must be proven in former applications
   - Safety and nonsafety functions must be implemented separately whenever possible (in software and, if applicable, in hardware) to avoid influencing the safety section.
   - Along with the standard system monitoring diagnostics (e.g., "watchdog" circuits), which return outputs to the safe state in malfunctions or failures, further system-specific requirements (fan monitoring, climate control, etc., as instructed by the manufacturer) are to be implemented.
   - Shutdowns may be implemented only via binary outputs. Resetting analog outputs to 0/4 mA is not acceptable as the sole shutdown action.
   - Reports of a safety function response must be distinct from reports of operating and monitoring equipment (e.g., different colors).
   - Application software must be created only by trained personnel, written in an easy-to-follow form (structured, modular software), and easy to test.
   - The safety portion of the application program must be subjected to initial examination by the persons involved, and by a specialist, along with the planning documentation.
   - When major changes are made in software, even in the non-safety-relevant portion, a functional test of the safety-relevant functions should be performed.
   - Scheduled functional testing should also include the current software status (application software and firmware), including software documentation.

Labeling. All important components of the PCE safety system must be labeled as such in the documentation, locally in the instrument and the control room.

Testing Before Commissioning. Before the PCE safety system is first placed in service, a test must be performed to determine whether its design and function comply with the provisions of the safety review. At this time, the documentation of the PCE safety system and the test instructions for periodic testing must be available.

Testing must be done in such a way that proper functioning is demonstrated in the interplay of all components. The first functional test must be documented in writing.

3.4.3.4. Operation of PCE Safety System

Organizational Measures. Organizational measures are required for the operation of the PCE safety systems. They fall into four groups:

Continuous monitoring (surveillance)
Inspection (functional testing)
Maintenance
Repair

Continuous Monitoring. Malfunctions of PCE safety systems must be detected by regularly observing process variables, and checking them for plausibility. Such observations are done by qualified personnel.

Outwardly noticeable defects or damage to the PCE safety equipment or their installations are identified by regular visual inspections, and must be immediately repaired.

Functional Testing. Functional tests are needed in order to reveal passive failure. Test instructions must be prepared, summarizing the nature and extent of periodic testing. These instructions must contain information on the nominal state and nominal performance of the safety device, along with a description of the properties and functions to be tested. This includes, in particular, statements of limiting values and measurement ranges, and other specified features to be inspected (such as actuating times for valves, time lags for trigger signals, and other properties important for the performance of the safety task). The testing procedure must be described in test instructions (e.g., checklists) that the checking personnel can understand. The limiting values must be documented in writing by the operations manager.

The test cycle is set in the general safety review. Differences in availability may dictate that some parts of a protective device be tested more often than others.

If no comparable experience exists, an appropriately short testing interval should be set at first. If the tests reveal sufficient safety-related availability, the test interval can be lengthened as the time in service increases.

By analogy with pertinent technical guidelines, inspection of the entire PCE safety system (from sensor to actuator) must take place at least once a year. The operations manager is responsible for seeing that functional tests are performed.

It is desirable that testing be done under conditions corresponding to the demand case and with the least possible modification of the PCE safety system. Whenever modifications are necessary to perform the check, special care should be taken to restore the PCE safety system to its proper state. If manual overrides are installed in multichannel PCE safety systems, only one channel at a time may be bridged.

Care must be taken that neither safety nor availability is substantially impaired during the test. The method used should start with the assumption that faults may be present in the safety device; thus suitable (e.g., organizational) measures should be taken to insure that the plant remains in specified operation.

Further details on testing, especially testing methods for PCE safety devices, are explained in VDI/VDE 2180, Sheet 4.

In addition, tests should be performed after long shutdowns and repairs to the device.

Maintenance. When service conditions are severe, or in the case of certain measurement techniques (e.g., process analytical instruments), scheduled maintenance may be necessary. Work schedules must be prepared summarizing the nature and extent of periodic maintenance, and the required permits from plant management. Maintenance operations are performed by qualified personnel in accordance with these work schedules, and the work must be documented.

Repair. Repair of PCE safety devices must be performed without delay by qualified personnel whenever defects are found in the devices, and there is no alternative that will maintain the level of safety.

Documentation. Testing, maintenance, and repair of PCE safety and damange control devices must be documented. In particular, documentation of functional tests must include at least the following information:

- Identification of test objective
- Results of test, with detailed information on faults corrected
- Date of test
- Signature of tester
- Signature of operations manager

The signatures of the tester (inspector) and operations manager confirm the release and ac-

ceptance of the functional PCE safety or damage control device. The test report must be retained for at least five years so that performance of specified tests can be proved.

Fault Analysis. To improve the reliability of protective devices, any faults discovered must be carefully analyzed; longitudinal documentation of test results reveals weak points. If the same causes are seen to produce faults again, this indicates a weak point and calls for improvement or testing at shorter intervals.

Decommissioning, Restart, and Change of Limiting Values. *Decommissioning and Short-Time Overrides.* If a PCE safety device must be temporarily taken out of service or bypassed, e.g., during plant start-up, this must be documented in writing. Other technical or organizational measures must be put into effect to insure safety while the device is out of service or bypassed. The decommissioning or override status must be clearly identifiable.

Appropriately labeled technical devices, e.g., key switches, can be provided when a safety device has to be bypassed repeatedly. A clear signal must be given to indicate bypassing; an automatic interlocking involving the bypassed PCE safety device must be released if necessary.

There are three options for restart, and these must likewise be documented:

1) Restart without functional testing (e.g., after overriding for calibration)
2) Restart with partial or special testing (e.g., after replacement of a unit, cable, or data line, or after correction of a malfunction). A complete test (as under 3) should be performed as soon as possible.
3) Restart with full functional testing, as provided in the testing specification (e.g., after prolonged interruption of service)

Restart after Initiation of Safety Function. Automatic restart after initiation of the safety function is to be "disabled," i.e., restarting must be prevented when the plant is placed in operation again. This applies particularly when the process safety variable has already returned to the normal operating range. Until the plant state has not been checked portions of the plant affected by the initiation of PCE safety devices cannot be returned to service by manual action. PCE devices used for restoring the PCE safety device to service are considered PCE operating equipment.

Setting Limiting Values. Limiting values for PCE safety systems may be changed only on the instructions of the operations manager, who must also determine the extent to which this action affects the results of the safety review.

A report must be prepared to document the change in limiting value (time of change, authority, person performing the change), and the correct setting of the new limiting value must be verified.

3.4.3.5. Summary

In the technical safety concept, non-PCE and PCE safety measures are employed to reduce the risk arising from a chemical process plant to a value below the limiting risk. The risk to be countered is evaluated qualitatively, and the result is used in "grading" protective measures by scope. Technical measures are implemented as safety systems.

The task of a PCE safety system is to reduce the risk at least to the limiting risk, possibly in cooperation with non-PCE safety systems or organizational measures. From the risk assessment and the associated requirements, safety requirements on PCE safety systems are first determined, and from these are derived the technical and nontechnical measures needed to fulfill the safety function. In a second step, graded measures are devised to meet the requirements. The requirements are more stringent the greater the risk to be covered by the PCE safety system.

3.5. Special Safety Equipment

3.5.1. Pressure-Relief Devices

3.5.1.1. Introduction

Liquids and gases in chemical plants are frequently held in vessels that can be closed. A variety of mechanisms (Section 3.5.1.4) can cause overpressure to develop in such vessels. Initially, the vessel walls withstand this overpressure, but if it exceeds some limit, the "maximum allowable working pressure," which depends on vessel

shape, wall thickness, and material properties, the vessel bursts and the fluid contained is released, unless some sort of relief device limits the rising pressure to the maximum allowable working pressure.

Figure 51. Safety valve
a) Valve disk; b) Flow area

Figure 52. Bursting disk
a) Disk; b) Holder

Classical devices that act automatically to prevent excessive pressure in pressurized compartments are the safety valve and the bursting disk (Figs. 51 and 52) [171–176].

Vents on tanks are operating equipment, not actual safety devices. Not until modern plants were built did their function change as artificial ventilating and gas-displacement systems were installed on tanks.

3.5.1.2. Safety Valves

A safety valve opens automatically when the set pressure p_0 of the valve is exceeded. The valve disk is lifted by an amount h and makes the flow area available for pressure relief. In general, the full lift is attained within a pressure rise of no more than 10 % above the set pressure. The disk reseats when the pressure has dropped below the set pressure. In this way, the amount of vessel contents released is only that needed for instantaneous pressure limitation.

The "opening characteristic" of a safety valve is described by the lift of the valve disk as a function of the pressure p in the vessel. This characteristic depends on the interaction of opening and closing forces on the disk. Opening forces are the pressure force on the disk and, after the disk begins to lift, the fluid dynamic forces exerted by the escaping fluid. These fluid dynamic forces are a function of the lift and strongly influenced by the geometry of the disk, which is designed to achieve a suitable opening characteristic. Closing forces are a constant weight or a lift-depending spring force and the back pressure on the valve disk, which is the sum of an external "superimposed" pressure and the pressure generated by the escaping fluid in the discharge line after the valve opens.

Figure 53 illustrates the interaction of opening and closing forces. Where the opening forces, as a function of disk lift at constant pressure, increase more slowly than the spring force, the valve can open only when the pressure rises further. In this range (A – B in Fig. 53), it opens continuously. If the opening forces increase more rapidly than the closing force (to the right of B), the valve opens abruptly along the constant-pressure curve, up to the next equilibrium point D or the full lift limit C. Similarly, as the pressure declines, the valve reacts by closing

continuously from C (or D) to E and on to F. It then closes abruptly (F – G) because the remaining opening forces at constant pressure and decreasing lift (to the left of F) are smaller than the closing force exerted by the spring. The pressure increase to achieve the full lift between A and C (or D) is the "opening pressure difference." The pressure drop between A and G is called the "reseating pressure difference," or "blowdown."

Figure 53. Lift – force – pressure diagram
See text for details

Specially designed safety valves have supplementary loads, which act as a function of pressure to reinforce the closing force until the set pressure is reached, or reinforce the opening force when the set pressure is exceeded. These loads can completely replace weights or springs. In the bellows-type safety valve, a bellows between the disk and housing largely eliminates the effect of back pressure on the discharge side.

Safety valves are classified by opening characteristic and loading principle. The *full-lift safety valve* opens almost abruptly to full lift within a pressure rise of $\leq 5\,\%$ above the set pressure, thereby attaining maximum discharge capacity very quickly. It also closes abruptly. The *proportional safety valve*, in contrast, opens continuously (though not necessarily linearly) as the pressure increases above the set pressure; it also closes gradually. There are no special requirements on the opening characteristic of the *standard safety valve*, and its performance falls between those of the full-lift and proportional types. With *weight-loaded* and *spring-loaded safety valves*, the set pressure must be significantly higher than the normal working pressure in the protected compartment so the valve remains tight during normal operation. The working and set pressures can be much closer together in *supplementary loaded* and in *controlled safety valves*, because the (controlled) closing and opening forces at the setpoint can change almost discontinuously. *Pilot-operated safety valves* have to be classed as controlled safety valves because of their construction and functional principles.

The full-lift safety valve is preferred when large volumes of gas have to be discharged suddenly. The proportional type adapts better to a fluctuating mass flow, and is well suited to low volume flow rates such as those resulting from thermal expansion, and also to variable flows of mostly incompressible fluids (liquids). Supplementary loaded and controlled safety valves are used chiefly in power plants, where large mass flow rates have to be handled and the generally constant service conditions make it possible to run the plant continuously at the limit of its design pressure. Because it permits good sealing of the interior space against the surroundings, the bellows valve is preferred with fluids that must never be released to the environment. It is suitable where back pressure in the discharge line is high or fluctuating, because it restricts the back-pressure effect.

The mechanical reliability and discharge capacity of safety valves are commonly determined by type testing. The discharge capacity is characterized by the certified coefficient of discharge α_w, which holds only for a range of set pressures established by type testing. Normally $\alpha_w = 0.6 – 0.8$ for full-lift valves and gaseous discharge fluids; for proportional valves and liquids $\alpha_w = 0.1 – 0.35$. Against the actual discharge performance, α_w includes a safety margin of ca. 10 %. Unauthorized changes made on a safety valve, affect the basis of the type testing and the discharge capacity is no longer certified. In particular, the installation of an incorrect spring can keep the valve from fully opening, even though the set pressure is correct, so that the required discharge capacity is not available.

For proper functioning, a safety valve must have the correct set pressure, and must be able

to discharge the maximum possible mass flow on opening. Spring-loaded full-lift valves tend to go into self-excited oscillation (chattering) when there are abrupt pressure changes close to the set pressure; the valve opens and closes at short intervals, and the discharge capacity is markedly reduced. Chattering of the valve disk damages the seat and possibly the entire valve, and tightness is impaired. To prevent chattering, the pressure drop in the feed line during discharging must not exceed 3 % of the set pressure. Chattering can also occur if the safety valve is too large for the mass flow rate it is to discharge. If chattering cannot be eliminated, the safety valve can be equipped with a vibration damper. A design modification to limit the full lift is also possible in oversized valves.

The discharge capacity is also reduced if the back pressure in the discharge line is too high. It should therefore not exceed 15 % of the set pressure, or 50 % for bellows safety valves.

3.5.1.3. Bursting Disks

A bursting disk is a closure element that fails when its "bursting pressure" is reached, leaving open the flow area of a discharge line. The design is governed by the construction materials.

Disks can be classified as follows:

Membrane-type disks are loaded by membrane stresses. They fail when the yield point is reached. *Brittle plates* are loaded by bending stresses. They fracture when the breaking stress is reached. The yield point and breaking strength are functions of temperature, so the bursting pressure varies with service temperature. *Shells of revolution* fail by buckling when a stability limit, governed by the modulus of elasticity, is reached (reverse-acting disks). The stability limit is less temperature dependent than the yield point and breaking strength. The bursting of the shell after buckling can be aided by special devices, e.g., a fixed knife in the form of a cross, located behind the bursting disk. The serviceability of bursting disks is determined by bursting-pressure tests on samples.

A bursting disk causes only a slight increase in the flow resistance of the discharge line; it opens spontaneously, and frees a larger flow area than does a safety valve of the same nominal diameter. It is thus particularly well suited to rapidly rising pressures and large volume flow rates. Bursting disks are less sensitive than safety valves to gumming and polymerizing media. They have the disadvantage that they do not reclose, and if a disk fails a large quantity of product can be released. Depending on the design, bursting disks are often sensitive to underpressure in the protected compartment and back pressure on the discharge side.

Membranes are employed chiefly for large flow areas and low overpressures. Panels are used when the corrosiveness or other properties of the medium dictate the use of chemically resistant materials, e.g., graphite, which are not appropriate for the fabrication of thin shells.

3.5.1.4. Sizing of Safety Valves

The protection of a plant section with a pressure-relief device such as a safety valve involves five steps:

1) Definition of scenario
2) Calculation of relief cross section
3) Valve selection
4) Determination of mass flow capacity
5) Impact analysis

The first step in defining the scenario is a systematic safety analysis of the plant section under consideration, e.g., in a HAZOP study. These scenario can be divided into two groups:

1) An energy or material flow is supplied from outside (physical action)
2) The energy or material flow is generated in the system (chemical reaction)

A simple systems analysis makes it possible to break the first group down further:

1) The system is heated. Pressure builds up as a result of thermal expansion, rising vapor pressure, or evolution of dissolved substances. The mass flow rate to be relieved depends on the maximum quantity of heat per unit time that can be supplied to the system.
2) A substance flows from a higher-pressure system into the system under consideration. The mass flow rate to be relieved depends on the rate at which mass can be delivered to the system.

3) A flow of matter is supplied to the system by a pressurizing device, e.g., a pump. The rate at which mass must be discharged depends on the delivery capacity of the pressurizer.

The second group includes systems in which an unacceptable rise in pressure would result if a reaction went to completion. The pressure rise can result from the increase in vapor pressure as the temperature increases, and/or from the liberation of gas, e.g., by decomposition of the condensed phase. Possible causes and mechanisms of such reactions are described further in Section 2.3, while Section 2.3.2 lists methods by which the progress of an exothermic reaction can be determined experimentally. As a rule, studies of this kind are essential in the design of a pressure-relief device. Useful findings include the rate of pressure rise and the rate of heat production. This forms the basis for determining the rate of mass discharge, and hence for designing the safety valve, with the help of fundamental hydrodynamic equations [171], [172], [177].

If the required minimum cross section of the valve is known, a valve is selected such that its smallest cross section is larger than the required value. The cross section gives the maximum rate of discharge through the valve, which makes it possible to calculate the pressure drops on the high-pressure and discharge sides of the valve. These are compared with the limits discussed in Section 3.5.1.2, which must not be exceeded.

It must also be determined whether two-phase discharge can occur. Correlations useful for this purpose have been published by DIERS (Design Institute of Emergency Relief Systems) [178].

Figure 54 illustrates what happens in a pressure-relief event with two-phase flow [179]. When the pressure in the gas space of a vessel is relieved, single-phase discharge occurs first; the pressure drops rapidly. The liquid cannot immediately react to this change of state with a corresponding drop in temperature, and becomes superheated. To restore thermodynamic equilibrium, intensified formation of vapor bubbles begins (after a boiling delay time). The growing and ascending bubbles both displace the liquid and entrain it, setting the contents of the vessel in upward motion. If the free surface of the liquid reaches the discharge opening, a two-phase flow results.

Figure 54. Pressure variation and behavior of vessel contents when pressure on the vapor space above a single-component mixture is relieved

This process depends on both the properties of the reactor contents (viscosity, surface, tension, foaming tendency) and the reactor geometry, fill level, and discharge capacity of the valve [178]. Thus low surface tension and high viscosity promote two-phase flow, while low fill level and a pressure-relief opening small in comparison with the vessel cross section help suppress two-phase flow.

Figure 55. Retention system with liquid separator and direct condenser
a) Reactor; b) Liquid separator with retention volume and cooling jacket; c) Direct- contact condenser with dip tube and cooling jacket

The development of two-phase flow has the consequences that more liquid is removed, more total mass is removed, and the mass flow rate is increased substantially. On the other hand, the gas/vapor mass flow rate that has to be discharged for safe pressure relief is smaller than in single-phase flow. This means that a valve designed for single-phase discharge can be un-

dersized for safe pressure relief under two-phase discharge conditions, and a new test must be performed for this case (the pressure drops on the pressure and discharge sides of the valve must also be remeasured).

The occurrence of two-phase flow can result in markedly higher inertial forces and momentum transfer.

An iterative procedure is usually followed until all constraints are met. A thorough discussion of models to describe two-phase flow has appeared in [180].

3.5.2. Blowdown Systems

3.5.2.1. Procedure

The substances discharged for pressure relief must be handled in such a way that they do not cause personal injury or environmental damage [181]. In general, it is necessary first to determine [178] whether the discharge flow is single-phase, gas/vapor, or two-phase. In the two-phase case, it is expedient to separate the liquid phase [182] and retain it in order to suppress any further reactions. When separation is accomplished in separate vessels, e.g., impingement separators or cyclones, the reaction is stopped by a large quantity of cold water, containing a reaction inhibitor if necessary. On grounds of space and cost, it is desirable to use one apparatus for both functions, if possible (Fig. 55) [183].

The safe removal of substances in gas/vapor form must also be insured. Three approaches to gas/vapor handling are possible, depending on the total quantity of the substances discharged and their properties [184]:

Discharge into the atmosphere
Retention by treatment systems
Retention in closed recovery systems

Substances may be released only if it has been demonstrated for the particular case, e.g., by a propagation calculation [185], that the impact of the released substances on humans and the environment stays within acceptable limits, otherwise, retention in treatment systems is necessary. Industrial treatment systems include thermal cleanup systems, flare systems, scrubbers, and dip-tube and other condensation units.

When systems of these kinds are employed, the first point to check is that the risk potential is reduced to an adequate degree, since both untreated residues and newly formed degradation products are released into the environment. The second point is whether the risk potential is merely shifted; a scrubber may clean up the exhaust air, but then generate highly contaminated wastewater. Finally, it must be demonstrated that the disposal systems are not harmed by the reaction forces and momentum transfer occurring during discharge.

If no satisfactory answers are obtained to these three questions, the substances must be delivered to a closed retention system [183], [186]. In the simplest case, they can be captured in a static vessel, or in systems that can be blown up, but devices of this type may quickly run into practical limits because the volumes of gas to be intercepted are often very large.

One way to minimize the volume needed is to dissolve or condense the discharged substances, or to fix them chemically. Often, this can be done by introducing the gases or vapors into a water-filled vessel [187]. The degree of condensation or absorption can be enhanced, and the necessary volume minimized, by spraying the substances into the vessel through nozzles or distributor pipes [188], [189]. Other variables affecting the quality of condensation or absorption are the temperature of the liquid in the vessel, the fill level, and the pressure in the retention system, which should be as high as possible, consistent with the requirements of the pressure-relief device (Fig. 55).

3.5.2.2. Alternatives

The safe design of a pressure-relief system combined with suitable facilities for handling the discharge can be a time-consuming iterative process. When costly retention or treatment units appear necessary, economic and environmental factors dictate that alternative pressure-relief arrangements must also be evaluated.

For example, pressure relief can be dispensed with if the vessel is constructed so that neither physical nor chemical processes can generate a pressure higher than its maximum allowable working pressure.

In addition, no pressure-relief device is needed if appropriate instrumentation and control [190] (Section 3.4.3) can insure that an unacceptable pressure rise cannot occur. These features must reliably control the reaction, or provision must be made to inject an emergency suppressor or emergency coolant to stop the reaction immediately [191].

Which solution is preferable can be decided only when the specific constraints of the application are known.

3.5.3. Flame Arresters and Explosion Barriers [192–201]

3.5.3.1. Introduction

The initiation and propagation of explosions in (chemical) plants where explosive mixtures are present can lead to significant harm to persons, the environment, and property. One feasible, and often economic, way to control and prevent such explosions in closed systems is to separate parts of the plant with flame arresters. These block the propagation of an explosion, and help limit and control its impacts. This type of isolation can be applied to mixtures of flammable gases/vapors and oxidants as well as explosive dust – oxidant mixtures.

3.5.3.2. Flame Arresters for Mixtures of Vapors (Gases) and Air

In normal plant operation, flame arresters permit the free passage of explosive mixtures. If ignition occurs, however, they block the passage of the flame, preventing the ignition from being transmitted to the protected side. The extinguishing action in present-day flame arresters, regardless of design, is based on one or more of three mechanisms:

Flame Quenching in Narrow Channels. Through intimate contact with the cold walls of a filter element comprising many narrow channels, heat and free radicals are withdrawn from the combustion process, and the flame is extinguished. This mechanism is employed in dry flame screens (e.g., the crimped-ribbon arrester shown in Fig. 56).

Figure 56. Cutaway drawing of a crimped-ribbon-type flame arrester [201]

Blocking by Liquids. There are two main types of liquid-type flame arresters, the liquid seal in the form of a siphon inserted in a liquid- conveying pipe, and the hydraulic arrester in which a stream of gas passes through a dip tube and is divided into noncoalescing bubbles. The siphon, by virtue of the configuration, is continuously filled with the conveyed medium (Fig. 57). Water is the most common barrier liquid in the hydraulic flame arrester.

Figure 57. Wet-type flame arrester (siphon arrester) [201]

Dynamic Blocking. The geometry of the flame arrester includes a narrow clearance, in which the flow velocity is always higher than the

turbulent flame velocity (combustion velocity) in the explosive mixture. Upstream propagation of the reaction is thus impossible.

Use of Flame Arresters in Practice. The selection of an arrester is governed by a variety of constraints. Only exact knowledge of the system to be protected can provide the basis for choosing suitable and economical units.

First, it must be established what parts of the plant are to be safeguarded against what effects, i.e.,

> What are the potential ignition sources?
> Is ignition due to external or internal sources?

This is crucial in fixing the location, installation direction, and layout for the arrester. Two applications must be considered for the layout: deflagration and detonation (i.e., coupled combustion and shock waves with rapid pressure rise); the type of protection chosen will depend on which installation is used. Under some circumstances, a run of a few meters of pipe is enough to allow detonation, so that detonation-type arresters are commonly selected for installation in piping. Deflagration-type arresters can be employed where run-up distances are very short, e.g., where tank vents to the atmosphere are to be protected.

In a second step, the construction of the flame arrester is considered. The properties of the medium being transported are important: contamination with solids, solidification temperatures (heatability, frost protection), and condensation or solidification of impurities from the stream.

Quenching-type flame arresters in some services may become contaminated and suffer corrosion; these devices need regular inspection and cleaning. It makes sense to install several such flame arresters in parallel so that one at a time can be bypassed. If even a few of the passages in an arrester become enlarged, or if the flame filter is incorrectly inserted in the holder, the unit may fail.

In the case of pipework not continuously filled with liquid, the wet types of arrester are desirable on grounds of maintenance and availability; these can be obtained in a variety of designs.

Hydraulic arresters are often used to protect contaminated exhaust air streams. Safe operation depends on correct sizing and design, as well as the use of suitable instrumentation for continuous monitoring of important parameters. An automatic alarm should be provided, together with automatic initiation of emergency response when limiting values are violated. Safety-relevant parameters of this type of arrester include a sufficiently high liquid level over the end of the dip tube, limitation of maximum air flow rate, monitoring of liquid temperature (frost protection), and monitoring of temperature in the gas space of the arrester. As a rule, buildup of contaminants and condensing species from the air stream necessitates continuous cycling of liquid in and out of the arrester. To prevent the formation of a continuous explosion channel by the bursting of explosive gas bubbles in the ascending cloud of bubbles – which would allow an ignition to get through the arrester – it is important to have a hydraulic arrester designed for maximum air flow rate and minimum dip depth.

For the correct design of the flame arrester, it is essential to know the maximum experimentally safe gap for the substance being handled. This parameter serves as the basis for classifying substances into Explosion Groups II A, II B, and II C. In Germany, for cases covered by the Flammable Liquids Regulation (VbF), flame arresters must be type-tested (type-approved) for the appropriate explosion group, and for one of the two layouts (deflagration or detonation). Type approval tests are done with appropriate mixtures of fuel and air. Any change in oxidant (e.g., oxygen or chlorine instead of air) and any increase in oxygen partial pressure can lead to a change in performance, which can be assessed only after further experimental tests. Where the VbF does not apply, Germany does not yet have a type-testing requirement.

The quenching of flame in an arrester presupposes adequate removal of heat from the reaction or flame zone. In some arrester designs, handling flowing explosive mixtures, heat removal may be hindered so that a flame can stabilize on the arrester. The filter element and piping may be heated to the ignition point of the flowing mixture, and the flame can be propagated through the arrester. As a rule, the only way to insure adequate heat removal is by using end-of-line ar-

resters. Experimental demonstration of the "endurance burning safety" (ability to prevent flame transmission for an unlimited time) is required. Any flame arrester that does not have this property must be expected to fail after stabilizing the flame for a certain time unless countermeasures are taken. Therefore continuous temperature monitoring (Fig. 58) is required, along with initiation of emergency functions (e.g., cutting off the gas stream).

Figure 58. Flame arrester with temperature monitoring and steam injection [201]
a) Electronics; b) Solenoid valve

The use of a flame arrester leads to quenching of the flame at the arrester. However, the pressure generated in the explosion must be safely accomodated through design features (pressure-proof design) in conjunction with adequate provisions for pressure relief.

Safety Concepts. The use of flame arresters to separate plant sections that are not proof against explosion pressure shocks or explosion pressures is just one of a range of concepts applicable to explosion protection.

As is usual in explosion protection, all protective actions are based on risk analyses, which call for countermeasures with appropriate availability, depending on the probability of occurrence of explosive atmospheres (classified in zones) and potential ignition sources. Even when flame arresters are used, the zone and the ignition probability must still be analyzed. As a result of this interplay of occurrence probabilities redundancy of flame arresters is necessary. The important factor is the number of independent protective measures (Table 14).

Table 14. Number of measures to prevent flame transmission

Ignition sources anticipated in plant	Number of precautionary measures		
	Zone 0	Zone 1	Zone 2
Normal operation (e.g., burner flame)	3	2	1
Failures that are likely to occur	2	1	0
Failures that are not likely to occur	1	0	0

German regulations mandate the use of flame arresters to protect non-pressure-proof plant sections in storage facilities and filling points for flammable liquids. Further details can be found in the Flammable Liquids Regulation [196] and the Engineering Code on Flammable Liquids (TRbF).

3.5.3.3. Flame Arresters for Dust – Air Mixtures

The flame arresters that have been discussed are not designed for use in plant areas and piping where there is a danger of dust explosion. Other approaches must therefore be employed in such cases. Among the means used for isolation are star-wheel feeders, active barriers with extinguishing media, rapid- closing valves (explosion valves) and doors, and explosion vents. These methods are described more fully in VDI Guideline 2263 [200].

The use of star-wheel feeders requires prior testing to determine the ability to prevent flame propagation, as well as to withstand the explosion pressure. In order that no smoldering product is transported into downstream parts of the plant, the star wheel must be automatically cut off (e.g., with a pressure monitor) in the event of an explosion.

When active barriers and rapid- closing doors are used, injection of extinguishing agent into the flame front or closing of the doors is initiated in a few milliseconds by a flame detector. Specialists must perform tests to determine

the effectiveness (speed from detection to response) in the real plant geometry, and the ability to withstand pressure. Explosion valves, acting without auxiliary sources of energy, close at the higher flow velocities occurring during explosive pressure relief, automatically blocking off pipe cross sections, and preventing the explosion from propagating.

When explosion vents are used, the formation of long flames and the release of large amounts of product, possibly of environmental relevance, must be anticipated.

4. Safe Plant Operation

4.1. Safe Handling of Chemicals

4.1.1. Introduction

Substances and formulations in the form of raw materials, intermediates, and finished products are employed in many branches of industry. Some substances and formulations have dangerous properties (see also Sections 2.1 and 2.2); these are referred to as hazardous substances.

When hazardous substances are present, safety precautions must be taken so that concentrations stay below the limiting values in the workplace air, so that employees do not come into direct contact with hazardous substances, and so that fires and explosions do not occur.

Measures must be taken to prevent upsets in operation. If upsets come about anyway, the threat to employees must be limited.

Systematic safety analyses should be performed to determine the measures required [202]. Hazard sources and the conditions for their activation are systematically and comprehensively examined so that the hazard potentials can be ascertained. The knowledge gained makes it possible to identify the necessary measures case by case.

Points to be considered in establishing safety practices include provisions of legislation, engineering codes, industry and factory standards, and safety information relating to specific processes.

Technical measures, including the selection of processes with the lowest possible hazard potential, should be favored over administrative measures whenever possible. Preference should go to practices that safeguard the employee or mitigate risks, regardless of employee behavior.

Despite many technical measures, ranging up to "enclosed" plants, contact of employees with hazardous substances cannot be completely prevented. Normal operation entails filling, transferring, and emptying media, taking samples, and cleaning and inspecting vessels. In abnormal operation, for example, substances can get into work areas by leakage and when pressure-relief devices operate.

Selected practices for the safe handling of chemicals are discussed in what follows. These should prevent the release of hazardous substances and threats to employees and the environment.

4.1.2. Normal Operation

Transferring, Filling, and Emptying. In the chemical industry, the handling of liquids is part of daily routine. Liquids must be drained from tanks, drums, and reactors, or masterbatch tanks and reactors must be filled with liquids. It is often necessary to meter exact quantities in specified times [203].

Preventing Hazardous Concentrations of Substances in the Gas Phase. Some ways to prevent hazardous concentrations are:

1) Transferring liquids in systems that are enclosed or can be equalized (e.g., fixed piping from storage tank to plant); to be employed especially when transferring carcinogenic, highly toxic, and toxic liquids
2) Using gas-displacement devices for pumping
3) Extracting vapors at the point of escape
4) Providing adequate ventilation at the workplace

Avoiding Escape of Liquids. While being transferred, liquids can escape by splashing, dripping, spilling, or overflowing. Some ways to prevent the escape of liquids are:

1) Restricting transfer operations
2) Selecting and properly installing suitable filling devices
3) Using appropriate designs for piping disconnections

4) Employing process-specific practices as well as instrumentation and control, examples being:
   Emptying into calibrated vessels
   Emptying through volumetric meters
   Running drain lines to installed scales

Avoiding Electrostatic Charging. Liquids can become electrostatically charged while flowing next to walls or when being sprayed, filtered, or stirred. Charges transported along with the liquid can charge vessels to the extent that static electricity is discharged at the liquid surface; this can result in the ignition of flammable gas – air or vapor – air mixtures. The amount of charging depends strongly on the conductivity, the flow velocity, and the quantity of liquid transported.

A high level of charging must always be expected when interfaces are present in nonconductive liquids, e.g., when immiscible liquids are transported, or when liquid mists or vapors are generated.

Liquids with conductivities $> 10^4$ pS/m do not acquire a charge while flowing.

Avoiding Mix-up of Liquids and of Containers. Dangerous reactions may occur if substances are mistaken for others. Mix-up can be avoided by:

1) Design practices; connections for vessels containing different liquids can differ in diameter from one liquid to another or be made with incompatible flange constructions (grooves, lugs)
2) Unambiguous labeling; vessels, piping, and connections for individual liquids can be labeled, e.g., with substance names, colors, or numbers
3) Identity checking before liquids are drained

Avoiding, Restricting, or Assisting Manual Transport Operations. Ways of avoiding transport operations include:

1) Fixed piping between storage tanks and consumer (reactor, tap); the preconditions for this is that pipe runs be as short as possible, i.e., all parts of the plant are arranged compactly
2) Mechanization of operations

Ways of restricting transport operations include:

1) Purchase of liquids in larger vessels, e.g., 1000-L containers instead of 200-L drums
2) Suitable placement of vessels and other measures to minimize the need for transfers

If manual transfers are unavoidable, off-the-shelf or plant-designed equipment can make them easier and thus less dangerous.

4.1.3. Sampling

Samples are required for the following reasons:

1) Determining identity and quality of feedstocks
2) Monitoring and controlling chemical reactions and other processes in the plant
3) Assessing quality of intermediate and end products

Employees conducting sampling operation may be endangered by hazardous substances and the sampling conditions [204].

Safe Design of Sampling Devices. The following points must be considered in the design of sampling stations:

1) The sample should be withdrawn at a point in the plant where the pressure and temperature are as low as possible.
2) The cross-sectional area of the sampling device must be kept as small as possible.
3) Sampling must be designed such that large quantities of hazardous substances cannot escape from a plant or part of a plant, e.g., because of a malfunctioning or damaged sampling device.
4) The inevitable pre-sample liquid must be returned to the closed system, as far as possible. Two points merit special attention: the sampling point should be designed such that there is no pre-sample flow, or the unavoidable pre-sample flow is safely returned to the processing system.

When the sample is transferred into the sample container, splashing, vaporization, dripping, overflowing, and escape of hot liquids must be prevented. It may be necessary to take steps to prevent static charging, such as:

If possible, avoid sampling from stirred vessels through the manhole (especially if the vessel contains flammable substances). Otherwise, turn off stirrer, sprayers, and other charge-producing components before sampling and wait for a "calming" time.

Do not allow to spray flammable, chargeable liquids into open sample containers, especially if partial vaporization of the liquid is anticipated.

If possible, conduct sampling of flammable, chargable liquids in a closed system only, e.g., in a nitrogen-purged sample vessel.

Limit the outflow velocity of the liquid; rule-of-thumb ca. 1 m/s.

Figure 59. Sampling with vacuum
a) Dip tube; b) Stopcock; c), d), e) Fittings; f) Container

Sampling with Vacuum. Figure 59 shows a setup for taking samples with no pre-sample flow. The procedure is shown by the numbers in the diagram:

1) Open ball valve (b)
2) Blow dip tube (a) empty through fitting (d) (e.g., with nitrogen)
3) Close fitting (d)
4) Apply vacuum to fitting (e) in order to draw product into container (f)
5) Close ball valve (b)
6) Close fitting (e)
7) Apply nitrogen pressure through fitting (c) to transfer sample into suitable vessel
8) Close fitting (c)

Nonreturn valves in the vacuum line prevent the working fluids in the vacuum generator from getting into the product vessel.

4.1.4. Cleaning of Vessels

Cleaning methods should be designed so that worker health is not endangered by residues, contaminants, or cleaning agents [205]. Before cleaning is begun, the status of the vessels to be cleaned must be determined. It must be known what substances, with what hazardous properties, are or have been present (solid deposits, liquids, vapors, gases).

Hazards can arise from:

1) Reaction of the cleaning liquid with residues and contaminants
2) Flammable cleaning agents
3) Static charging when liquids are sprayed under high pressure
4) Materials unstable with respect to the substances, pressures, temperatures, and mechanical stresses present

The proper precautions must be ascertained. Cleaning must be performed by trained personnel under expert supervision, in accord with written information. The cleaning method must be described in an instruction manual.

Whenever possible, closed cleaning systems should be used.

4.1.5. Safety Practices when Working with Hazardous Substances Under Abnormal Operation

Safety practices must prevent employees being exposed to excessive concentrations of hazardous substances, even in abnormal or upset operation. Pressure vessels and pressure piping

must be designed, constructed, and operated in such a way that personnel and third parties are not endangered. The action of pressure-relief devices must not threaten employees or third parties. The quantity and nature of the substances present may make it necessary to conduct releases to the atmosphere or to provide supplementary features, e.g., scrubbers, flare systems, or blowdown tanks.

Leaks represent a further source of danger to personnel and the environment.

Seal systems installed on shafts of pumps, drives, mixers, stirrers, etc. must be selected in accord with the media present and the regulatory requirements [206].

Along with proper design, the effectiveness of the seal systems must be tested regularly, and any leaks must be detected. When media are under pressure, splash deflectors must be used.

Technical protective practices must also be coordinated with administrative and personnel practices, especially for the case of abnormal operation.

4.2. Safety in Batch and Continuous Processes

4.2.1. Safety in Batch Processes [207–210]

4.2.1.1. Introduction

Safe production imposes stringent requirements on the owners and operators of chemical plants, who must observe and implement a body of legislation, rules, and regulations. What is more, the manufacturer of chemical products must make compromises between productivity, quality, safety, and environmental protection, but safety must take priority.

The principles of safety and environmental protection are established by management in accordance with the pertinent laws. Every chemical process involves a special combination of chemicals, equipment, and process conditions.

Safe operation makes it essential to study each process separately. The written set of instructions, the operating manual, occupies a central place in the safety effort.

4.2.1.2. The Operating Manual

Principles. The operating manual is a comprehensive document that fully describes a particular chemical or physical process used in making a product. It must guarantee that the process can be carried on in a safe, environmentally benign, economical, quality-oriented way.

A fundamental requirement is that the manual must describe in full scope and depth the steps that must be performed in the process. It must be unambiguous in that the employee at the workplace knows at all times precisely what actions are to be taken, in what order (e.g., numbering of steps). In extreme cases, every detail of a manipulation may have to be described.

While the manual must be exact and complete, it must also be easily understood. It may be expedient to write separate SOPs (standard operating procedures) when complicated and extended actions must be repeated for each batch (e.g., preparation of a hydrogenator).

Aids. The operating manual is based on a wide range of documents and other information sources (Fig. 60). For reasons of bulk, it cannot include all this information down to the last detail; a vital task of the author is to set priorities and to pick out specific points about a process and set them apart from what is obvious. Operators of multipurpose plants face a special challenge, for they must diagnose continuously varying conditions in the same apparatus and decide what process-specific information and actions are appropriate for each case.

Electronic data processing systems are nearly universal today, and the use of standard forms makes it possible to prepare the operating manual in a consistent way and present it in an easily understood fashion. Modifications and additions can be done quickly (e.g., if production is to be shifted to other plants).

The author of the manual must harmonize process data with plant-specific features while observing all guidelines on safety, environmental protection, occupational health, etc. Many documents and other information sources can be used as aids in describing the process, but it is not enough merely to have these to hand. They must be correctly interpreted and applied. A plant manager often finds it difficult to read documents written by specialists in other disci-

Figure 60. Operating manual: documents and information sources

plines (e.g., some chemists find technical plant flowsheets incomprehensible). Close cooperation with these specialists is needed to insure safe operation. The following information must be checked for completeness:

- Correctly acquired and interpreted material and process safety data
- Knowledge about the plant (cooling capacities, construction materials, plant status, etc.)
- Problems of high-technology facilities (automation, measurement and control, process control engineering systems)
- Limitations of technical safeguards (safety equipment)
- Utilization of infrastructure (energy supply, alarm systems, emergency systems, gas emission, wastewater, etc.)
- Correct and complete risk analysis (process and plant) and transfer of results into practice

For some plants or chemical processes, further points may have to be added to this list.

A good operating manual is never the product of one individual; it can be created only based on effective collaboration among specialists. As soon as the definitive operating manual is in being, the involved departments involved should apply their special knowledge to prepare opinions on the process. It is desirable to set up a fixed routing (toxicology/occupational health, safety, environment, registration, etc.) and have each activity signed off on the manual.

Contents and Organization. The organization of the operating manual is dictated by company policy, and there is no universal rule. The following three-part breakdown has been tested in practice:

1) Information section: intended chiefly for management; a quick overview of the process, presenting all safety-relevant aspects
2) Operations section: focused on the operating procedures; containing all information needed for the practical conduct of the process in the plant
3) Appendixes: data, details, and special information on the process; can be used to gain a deeper understanding of the process

A possible table of contents reflecting this overall breakdown is shown below.

Overall Organization of Operating Manual
Information Section

A. Changes from Precedent Operating Procedures
B. Chemical Scheme of Process
C. Materials (Chemicals, Yield)
D. Environmental and Safety Aspects
  D.1. Safety Data
  D.2. Summary of Risk Analysis
  D.3. Waste Disposal
  D.4. Environmental Impacts (Ecogram)
E. Plant and Equipment
E.1. Flowsheet (Streams in Apparatus)
E.2. Apparatus List
F. Material Data
G. Safety and Occupational Health
  G.1. General Provisions
  G.2. Process-Specific Provisions
H. Response to Accidents, Fire Alarms, Power Outages
Operations Section
I. Process Performance
  I.1. Step-by-Step Description
  I.2. Process Instructions
  I.3. Process Deviations, Remarks
J. Intermediate and End Product Inspection
K. Packaging and Storage
L. Equipment Cleaning on Product Changeover
Appendixes
M. Safety Tests, Wastewater Analyses, Operating Instructions for Individual Apparatus, Distribution List

Safety-relevant items are discussed as follows.

D.2, *Summary of Risk Analysis* gives a quick overview of the risks involved in the chemical process and the apparatus used. Known major risks are described along with key safety practices for the process. These include administrative practices, special technical safeguards, and important limit values (temperature, pressure, etc.).

G.1, *Safety and Occupational Health: General Provisions* lists general directives and rules to be followed in the chemical process. These may relate to reporting of deviations from the operating specifications, grounding, inert gas blanketing, etc. The instructions and rules must be formulated so that they can be observed in practice.

G.2, *Safety and Occupational Health: Process-Specific Provisions* gives detailed information and practices derived from the risk analysis. It may include special characteristics of equipment, special protective measures, handling of hazardous chemicals, increased risks, temperature limits, etc. This section is crucial for the operating personnel, telling how this process differs from others. It is especially important in multipurpose plants where the hazard potential varies continuously.

H, *Response to Accidents, Fire Alarms, Power Outages* is one of the hardest sections to write because problems often occur where they are least expected. With the help of the risk analysis, the steps in the process are analyzed, device by device; the analysis suggests what problems may occur and need to be considered in the planning of emergency response practices. Critical quantities are temperatures, times, and mixing; these conditions have to be determined separately for a variety of potential events. Practices are defined for each step in the process so that any kind of deviation can be responded to and the process returned to a safe condition.

I, *Process Performance* is the heart of the operating manual. The sequence of operations is detailed and described in chronological order. Sequential numbers are assigned to the process steps, which must be formulated in a clear and unambiguous way. The process conditions to be maintained and the quantities of chemicals to be used are written down as nominal values; the person controlling the process must acknowledge these in the form of actual values. When key reactants are present, or when process conditions are especially safety-relevant, it is desirable to confirm maintenance of the nominal values by having a second person (possibly a supervisor) take readings and sign.

In multipurpose plants, the base settings of the apparatus take on central significance for safety. The frequent changes of conditions in a given apparatus mean that adjustments must be made as a function of process conditions (temperature limits, stack gas downstream of scrubber, or stack gas cleanup unit, etc.), and some apparatus may have to be modified (cartridge filters, charging hoppers, etc.). Before a piece of equipment is placed in service, these base values must be set and checked.

The operations to be performed may be identical for a number of apparatus items (e.g., charging of a centrifuge). In such cases, reference may

be made to separate operating instructions or unit operation instructions (SOPs). When this is done, all that has to be set down step-by-step are the parameters specific to the process (e.g., speed of a centrifuge).

I.3, *Process Deviations, Remarks* is a form, to be completed on site for each batch. It helps in documenting irregularities in the process. The plant manager thus has a powerful tool for early detection of safety-relevant excursions; a shift log serves the same purpose.

L, *Equipment Cleaning on Product Changeover* is very important. From the safety standpoint, it is essential to describe the individual process steps chronologically and in detail, precisely as in I, *Process Performance*. It is a mistake to think that cleaning with water is completely harmless; if, for example, warm water is run into a reactor thought to be empty, solvent residues in the vapor phase may reach an explosive concentration. The mechanical removal of tenacious crusts with various tools can be critical if solvent residues are still present. It is therefore important that all safety principles are observed, even when cleaning the equipment.

Appendixes give standard operating procedures (SOPs), checklists, piping and electrical diagrams, etc. The exact distribution list is also important, because such a list is the only way to make certain that changes are made in all existing copies of the operating manual.

Introduction of a New Operating Manual. Careful, comprehensive documentation is just one important condition for safety in chemical production. Equally important is that employees properly understand the instructions. Often, the use of technical language and foreign words in the operating manual places it at too high a linguistic level for the workers. It is also remarkable to see the wide range of interpretations different people can put on imprecisely formulated directions! Another problem arises when some employees are not fluent in the language of the instructions, and thus fail wholly or in part to understand an exact description. Any new operating manual must be presented and explained, one step at a time, by oral instruction. Actions that are difficult to describe in speech or writing must be demonstrated in the plant. The objective of such training is not simply that the staff understand the instructions; as comprehension grows, so do acceptance and safety awareness.

The instruction program must end in a test to ascertain whether the operating manual has been understood. This can take the form of a game or competition, or can be administered as a moderated discussion. Another proven method is to have the employees make a display, illustrating and explaining the steps in the process.

4.2.1.3. The Human Aspect of Safety

Responsibility. The chemical process employee works in an environment with a substantial hazard potential. Every day brings the need to work with harmful substances, dangerous reactions, and large quantities of chemicals. Each employee thus bears a high degree of responsibility for co-workers, the environment, and the plant. Even small mistakes can lead to grave accidents. In multipurpose plants, the situation is even more critical: Processes differing in their demands on work methods and safety are performed in succession. Close concentration and an ability to adapt quickly to new conditions are required.

One of the most urgent tasks for management is to provide each employee with the conditions for safe work and the resources for performing the job. Occupational safety becomes a task for management, to insure that workers are safety-motivated, and to aid them in carrying out their demanding tasks with discipline and self-confidence – and without accidents.

Training. The training of plant operating personnel is a continuing task for plant managers. Thorough training greatly enhances on-the-job safety by helping workers to deal better with the pressure of responsibility, and to react calmly and correctly in stress situations. Training must be related to practice in the plant; an ideal example is discussion of the operating manual before production is started.

Special attention must be focused on the training of new employees, who possess good technical knowledge, but not the specific skills for their jobs. During their first months, these employees must be given technical orientation and support so they can perform in accordance with safety rules.

A particularly important point in training is how to respond in abnormal situations. In the context of the operating manual, responses must be explained in the clearest possible way. Practical and theoretical emergency training (e.g., with simulator programs) help establish a routine for dealing with abnormal conditions. It is important to instill in the worker the self- confidence that will lead to calm, considered actions in a real emergency.

This training is documented and evaluated. Feedback, including worker self-assessment, helps reveal gaps so that the appropriate steps can be taken.

Motivation. People are not inherently motivated to work safely; external motivation must be provided. Repeated use of convenient, but unsafe, work methods, not immediately leading to an accident, gives rise to bad habits. Administrative measures (e.g., checkups) and technical precautions can evoke safe working methods, and make unsafe behavior difficult or impossible. Correct behavior should be associated with all possible advantages: recognition, easier job performance, higher qualifications, etc.

Cooperation. In the course of time, process workers accumulate much practical experience. It is essential for plant management to make use of this knowledge by integrating the workers in the safety process. It is an important distinction whether the wearing of protective clothing and respirators is ordered or self-prescribed by a group within the plant working on a safety problem. Safety awareness, and above all the acceptance of key safety practices, can be markedly enhanced in this way.

4.2.1.4. Internal Organization and Policies

The processes that follow one another in a multipurpose facility call for intensified administrative policies. Without clear direction and clear structures, an operation where products are changed over, say, weekly slides into chaos, and an accident becomes inevitable. In what follows, some points are listed that should help avoid such problems.

Weekly Program. The weekly program provides a quick survey of planning for the next week. It yields information on personnel allocations, production program, maintenance activities, and special events. The weekly program is presented orally to the operating personnel and is posted in the plant. Every worker can then make the optimal preparations for coming assignments. Surprises and improvisation are largely eliminated.

Weekly Conference. All employees take part in a brief conference every week. This is an occasion for comments on the preceding week and the coming one, and is also very important for exchanging safety information. Absentees must be identified and informed later.

Shift Change. A formalized shift change must be instituted, so that the chemical process can be carried on without pause. The procedure should include explicit allocation of tasks, provided in writing if necessary (e.g., in a shift log).

Responsibility. Clear structures in work allocation is essential. The chain of command (hierarchical levels) must be preserved. Unless a situation arises calling for prompt intervention, the plant manager should issue instructions to process personnel only through supervisors and team leaders.

This avoids, the confusion generated by instructions and counterinstructions, and by indistinct areas of responsibility.

Monitoring of Administrative Practices. Procedures on paper are not enough; they must be carried out. Spot checks should be done to find out whether selected points in the operating manual are being complied with. Above all, misunderstandings and gradual safety-relevant changes in work procedures must be detected promptly.

Information Wall. An information or notice wall can be used to promote safety awareness, but this can fulfill its purpose only if it is actually read, so it must be prominently located. Attractive presentation (generous use of color, graphics, etc.) makes it more likely that employees take an interest in the information, but no information wall can replace the oral communication of important instructions.

4.2.1.5. Safety in Production Practice

Before the Start of Production. The saying "as you make your bed, so you must lie on it" takes on great significance when preparations are being made for a new process. The decisions made at this stage must lead to safe, accident-free operation later. Serious preparation is particularly important in multipurpose plants where chemical processes change frequently, so that the plant must continually be modified to fit changed process conditions and operations. Plant personnel must also adapt. There must be a distinct "breathing space" between finished and following production. Overlap allows the possibility of confusion, and increases risk.

Central importance attaches to the production conference with all employees concerned. The operating manual is reviewed step by step and supplementary instructions are given by management. This production conference is an intensified form of the conference discussed under the heading *Introduction of a New Operating Manual* at the end of Section 4.2.1.2. Its timing has much to do with its success; it should be held immediately before the start of production, so that employees can concentrate on the new process without distraction, and get themselves mentally set for it.

The preparations for a production changeover are extensive, but identical in their main features. It is worth standardizing these procedures; ideally with a checklist.

Checklist for Production Preparation

1) Information for leadership
   - Scope and timing of production
   - Study of process documentation
   - Leadership conference
2) Operating manual
   - Check operating manual (validity, changes)
   - Make available report forms
   - Post necessary documents (e.g., chemical data sheets) in plant
3) Feedstocks
   - Verify availability of reactants required
   - Verify quality of reactants
4) Training
   - Conduct process-specific training
   - Discuss process with all employees concerned
5) Plant/facilities
   - Check maintenance completed
   - Carry out functional tests
   - Install additional safety features
   - Make piping hookups according to diagrams
   - Perform leak tests
   - Check cleanness of equipment
6) Trial run
   - Carry out and document trial run with solvent and prepare report
7) Analysis
   - Prepare analytical sampling
8) Administrative
   - Order necessary placards and labels
   - Prepare folders and forms for process documentation
9) Wastes
   - Check disposal system
10) Storage
    - Prepare packages/containers
    - Set aside storage capacity
11) Safety
    - Verify completeness of safety documentation
    - Consider safety and occupational health checks

During Production. In a correctly prepared start-up, the management concentrates on inspections, monitoring work procedures, and verifying process safety. This task includes:

Surveillance of Action on the Shop Floor. It is obvious that a safety problem exists when the author of an operating manual is convinced that the instructions are being strictly followed while, for whatever reason, something entirely different is going on. The comment, "That's what it says in the book, but we've always done it differently," must not be tolerated. Discrepancies should be identified and immediately corrected.

Detection of Irregularities. A permanent task for both leadership and operating personnel is to identify process irregularities promptly; an important aid is a form for reporting process excursions. Prompt response to irregularities is a key element in accident prevention.

Assessment of Process Modifications. If deviations from the process instructions are necessary (e.g., because of defective apparatus), the plant manager must consider carefully the safety

consequences of such a change. If a distillation is carried out in a different piece of equipment under the same conditions, but the reactor jacket offers worse heat transfer, or the stirrer is less effective, the operation may last longer than specified. This type of change can lead to a dangerous condition.

Feedback. To obtain feedback on the practicability of an operating manual, it is essential to make contact with the workers at the workplace. An amazing amount of information and suggestions can be conveyed in a short, relaxed conversation.

Working Conditions. Noise, heat, uncomfortable posture, and other conditions can strongly affect human performance; working conditions should continually be examined and improved.

At Termination of Production. When a process is terminated, extensive process documentation is generated: production reports, analysis reports and certificates, printouts, etc., as well as a report summarizing all vital aspects of the process. This documentation yields information on potentially safety-relevant deviations in process chemistry and technology.

Process Documentation

1) Title/production stage
   Product, reactant, duration
2) Operating manual
   Applicable operating manual, deviations from valid procedure
3) Production
   Technical and chemical feasibility
4) Yields
   Comparison with earlier productions
5) Analysis/quality
   Remarks on product and reactants
6) Modifications/remodelling
   Summary comment
7) Economic aspects
   Calculation
8) Documentation
   Identification of changes, defects, and missing or outdated documents (e.g., safety tests); all changes made in flowsheets and other schemes in the course of repairs
9) Conference notes on termination of production
   Proposals for improving safety and process conditions

Good process documentation guarantees continuity of production with regard to work procedures and safety. Reading these documents when the same process is resumed is an absolute must.

Finally, the operating manual must be revised on the basis of the process documentation and, if necessary, rewritten. This insures that the manual reflects the reality of the plant and is ready to use for a new production at any time.

4.2.2. Safety in Continuous Processes

4.2.2.1. Introduction

A continuously operating production plant usually makes a single product. The steps involved can include both chemical reactions and physical separation operations. The quantity of material involved in both cases can be extraordinarily large, and special care is required, particularly when the substances have dangerous properties (flammable, explosive, toxic, or environmentally harmful). Continuous production plants are highly automated, and are seldom run without process control systems. Apart from start-up and shut-down modes, they operate according to fixed, specified process parameters. Intervention by operating personnel is necessary only during indicated or infrequent deviations from normal operating conditions. Because the process does not change, the danger of neglecting to readjust safety-relevant process variables on a change of product is not crucial. Typical continuous processes are:

– Refinery processes
– Cracking processes for olefin production
– Polymerizations
– Processes for making organic and inorganic bulk products

4.2.2.2. Analogies with Batch Processes

While the objectives, procedures, and plant sizes in the batch case are much different from those in the continuous case, quite a few of the basic statements in Section 4.2.1 also apply to continuous processes.

For example, exact knowledge of the process steps is important for process safety, in particular the acceptable deviations from the specified process parameters. The safety parameters and their acceptable ranges, established before the process plant is designed, must be set forth in an operating manual, and embodied in safe procedures for use by the operating personnel. In the context of risk or safety analysis (Section 3.3), the conditions for the occurrence of conceivable upsets must be identified, the consequences must be analyzed in terms of occurrence probability and severity, and appropriate safety practices must be instituted and covered in detail by bulletins and training of operating personnel. These studies must include not only the failure of technical devices (compressors, pumps, mills, and centrifuges) along with malfunctions of instrumentation and control devices, but also errors made by operating personnel, and partial and total power outages.

There must be a plant emergency plan, prescribing how workers should respond to a variety of abnormal conditions and accidents. A higher-order emergency and hazard- control plan dealing with major accidents, i.e., those that can pose a serious danger to employees, the immediate neighborhood of the plant, or the environment, must establish internal report routing and hazard- control measures. This plan must also designate those accidents in which external assistance, e.g., the public fire brigade or disaster response teams, must be requested, and what public institutions, e.g., the police and regulatory authorities, are to be informed, immediately or later.

Before production is started, operating personnel must receive training and orientation based on:

Process documentation:
- Process flowsheet
- Chemical reactions
- Physical steps in the process
- Parameter values to be maintained
- Safety rules
- Functioning of the process monitoring system

Safety information:
- Working with dangerous substances
- Use of personal protective equipment
- Periodic activities in the plant

Operating and safety instructions:
- Proper operation of apparatus and machinery
- Repair procedures
- Response to abnormal events

This information must be presented to all employees before they take up work in a plant, and at regular intervals thereafter. It is essential to test whether the knowledge presented has been understood and whether it can be promptly and correctly put into practice in stress situations. When the plant is being shut down on purpose, it is recommended that the shut-down process be combined with a simulated emergency.

Another vital activity in continuous plants is the keeping of a shift log. This helps inform later shifts about all important events in the plant. It is documentary in character, and must contain the following items:

– Bulletins from management
– Process upsets
– Deviations from normal operation
– Defects found in the plant
– Repairs needed and those completed
– Availability of standby equipment and machinery
– Warnings from supplier and customer plants

4.2.2.3. Special Features of Continuous Processes

Usually, large quantities of materials are involved in continuous processes. Large quantities, especially of flammable gases or toxic liquids or solids, represent high hazard potentials that must be taken into consideration when starting up the process for the first time or restarting after a temporary halt, during operation, and in the shut-down phases.

A continuous process has the advantage of inherent safety. While reactors have large dimensions and high throughputs, the quantities of products directly involved in the reaction and the holdup in the reactor are small; the hazard potential due to the reaction is minimal, especially for strongly exothermic reactions.

Continuous plants must be carefully inspected before they are first brought on stream:

1) All installation work, including subordinate work such as steam-trace lines and thermal insulation, has been completed
2) Scaffolding has been removed from the plant
3) Craft workers and assistants not actually needed in starting up the process must have left the plant
4) The entire system (logically subdivided into functional units) has been pressurized with gases (air or nitrogen) or liquids (water or harmless products) and checked for leaks
5) Auxiliary loops, coolers and chillers, special product or scrubber circuits, cleaning loops, and the wastewater and waste air cleanup units have been put through successful test runs
6) All instrumentation and control equipment, particularly their safety-relevant and fail-safe functions have been subjected to functional testing by qualified specialists. These functional checks must include not only the operation of alarms and safety interlocks on partial or total power outage, but also the emergency shut-down systems for plant sections or the entire plant

Almost all large continuous plants are now run with computer-assisted process control systems. Operating personnel must be thoroughly trained in the use of these systems so that they can take the proper risk-reducing actions in case of trouble, even in stress situations. Safety-related circuits are commonly hard-wired in parallel with the process control system. Switch points (temperatures, pressures, quantities, flow rates) are then fixed; they may be changed only after plant management and/or a safety expert has performed a safety analysis and issued a written directive. Where safety circuits are integrated into the process control system, technical or administrative policies must insure that safetyrelevant switch points cannot be altered by operating personnel on their own authority.

When starting up a continuous chemical process, special attention should be focused on "priming" the reaction. The pressure, temperature, quantities, and concentrations of reactants or catalysts must meet the criteria specified for the start-up phase. To avoid dangerous conditions due to delayed reactions and the associated buildup of unreacted feeds, the reaction start should be precisely monitored for rates of change (e.g., temperature or pressure rise) or with real-time analytical methods. If irregularities are seen, the reaction start should be interrupted, the fault identified and remedied, and the plant readied for another attempt. Many process control systems have sequence controls programmed to halt start-up automatically if an upset occurs.

During on-stream operation, the plant personnel continuously observe the process parameters, comparing them with the acceptable nominal ranges. Analyses of intermediate and end products not only help keep the commerical product within specification, but also provide information for use in maintaining the process. In particular, buildup of undesired byproducts due to recycles within a process or in closed- cycle scrubber units must elicit a high level of operator attention, and lead to countermeasures if appropriate.

Important process parameters that are recorded or stored by the process control system must be retained for up to ten years (depending on legislative provisions). These can be used to demonstrate that the process was run properly, or to prove compliance with emission limits and other air and water pollution control standards during regulatory audits; they are also indispensable in post-accident reconstruction.

As a rule, a continuous plant is shut down once a year for cleaning, inspection, and major repairs. After the process is stopped and before these operations are started, the plant must be carefully drained, purged, and cleaned according to the operating manual. For especially hazardous work (entry into vessels and tight spaces, or welding in plants that process flammable or explosive substances) plant management must establish safety practices that must be specified in detail in written work permisssions given to the employees performing the jobs. Exact instructions for the performance of repairs must be given (see Section 4.4).

When several craft teams are working at the same time, a coordinator must be designated to prevent them from endangering each other. The coordinator plans the work in time and space and is authorized to issue instructions to the craft teams.

Large continuous plants where explosive, flammable, acutely toxic, or environmentally harmful substances are handled in such quan-

tities as to create a high latent hazard potential present a special concern. Such a plant should have a rapid-response service, organized at each key level of the hierarchy, which can provide expert advice to emergency workers, to minimize the consequences of an accident.

4.3. Technical Inspection [211–217]

Introduction. In what follows, the term "technical inspection" denotes the inspection of technical devices by independent third parties; its purpose is to find out whether the equipment meets requirements set forth in legislation, regulations, or standards. In this way, unacceptable risks to employees working with the equipment – and to third parties and the environment – are prevented.

Plant hardware subject to technical inspection includes pressurized systems (vessels, piping); storage facilities for flammable substances or water pollutants; elevating, hoisting, and conveying equipment for the transportation of persons or freight; electrical equipment; nuclear facilities; means of transport such as automobiles and trucks, railroads, ships, and aircraft; power plants; petrochemical plants; and chemical plants.

Experts. As a rule, inspection is performed by an expert recognized by the responsible authority. Conditions for recognition include not only personal integrity, but also appropriate specialist qualifications (through education and continuing education), and it must be determined that the expert is not subject to instruction or restraint having to do with the inspection activity, i.e., independent.

The specialist qualification is generally a natural science or engineering degree. In many cases, a specified period of employment in the field is also required.

The expert may also be required to take part in an exchange of experience, which has two purposes: to assure consistency of technical inspection, and to identify crucial points of concern for a certain type of technical equipment. The results of such an exchange can also provide a basis for technical progress, and serve as input for standards development.

The role of the expert in technical inspection has long been established in Germany. The high point of the independent expert tradition was the field of law dealing with facilities "subject to surveillance." The experts recognized in this area are usually comprised in Technical Inspection Boards (TÜVs), which have in turn combined (along with some industrial firms that support their own inspection services, staffed by recognized experts) in the Association of Technical Inspection Boards.

Official recognition as an expert used to be limited to an individual on the German system. At European level, organizations will be entrusted with the performance of safety tests in the context of equipment manufacturing. Such organizations, after gaining accreditation at national level, can apply to the European Commission for "notification". These inspection organizations or "notified bodies" are to be engaged by manufacturers, especially for certain conformity tests pursuant to EU directives. The requirements on notified bodies are set forth in the Directives and relate chiefly to independence, personnel and hardware resources, and employee training. While expert inspection in Germany has been handled on a regional basis, notification as a testing service is valid throughout Europe, i.e., a laboratory accredited by a European Union member country and notified by the Commission can also do the pertinent conformity tests in the other member countries.

German Federal Water Quality and Pollution Control Act (Wasserhaushaltsgesetz) is following a similar path. Where tests by experts used to be prescribed, jurisdiction is shifting to inspection organizations, whose recognition in one Federal State is valid in all states.

Legal Background. The purpose of technical inspection is to make certain that the equipment inspected satisfies the quality and operational requirements set forth in regulations and standards.

Regulations are based on legislation that designates goods for protection and identifies technical devices to be regulated. The legislature thus authorizes regulatory bodies to set requirements, e.g., quality, operation, and inspection. Administrative actions such as permits and approvals are also authorized in this way.

A regulation commonly defines the scope of application, defines exceptions, states what technical devices are covered, establishes the scope and intervals of inspection, designates the persons or institutions that perform the inspections, and states what agencies have surveillance authority. The requirements set forth in such regulations are then implemented in instructions to the agencies or in engineering codes developed by private or public standardization bodies.

The harmonized European standards promise to be of great importance in this respect. These standards implement the basic safety requirements stated in European directives. Although their application is voluntary, they allow the presumption that a technical device complying with the harmonized European standards also fulfills the essential safety requirements of the pertinent directives.

Expert Inspection. Inspection and testing by the expert usually takes place in two phases. In the first, the existence and completeness of all necessary documents for the technical device are verified (official approvals, type approvals, type test certificates, certificates covering the inspection and use of materials, technical drawings and plans, operational descriptions, and reports from individual tests already performed). The second phase comprises the actual testing of physical facts.

The process of expert inspection can also be broken down in time. The first point examined is whether the design being inspected is suitable for the intended service. In the second phase, it is determined whether the technical device as fabricated complies with the submitted and examined design.

The next step is to verify that the finished technical device is operated in such a way that no stresses are imposed on it other than those considered in the first phase. An integrated system analysis may be called for here, especially if interaction with other technical devices or within the system as a whole must be taken into account. Finally, after a set inspection interval has passed, so- called periodic tests are conducted. These verify whether changes in the technical device due to its service, e.g., those resulting from wear, suggest that the stresses experienced in the next inspection cycle may no longer be tolerated. Another question at this stage is whether there have been safety-relevant changes within the system in which the component is integrated.

In addition to inspections before and during service, technical devices may also have to be inspected after they are taken out of service, if significant danger can result from improper operation.

When technical devices or their service conditions are modified in such a way that there may be safety-relevant effects, a new expert inspection generally has to be performed.

Finally, the responsible agency can instruct the expert to assess departures from the regulations or to investigate accidents.

The methods used in technical inspection range from simple visual examination to complex, specialized testing methods such as nondestructive ultrasonic tests or electron microscopy in connection with accident investigations. Such tests are generally performed, and the results interpreted, by specialists acting in support of the expert, who evaluates the results and cites them in the final report.

Integrated Plant Inspection. The interdisciplinary efforts of specialists in assessing safety problems is particularly important in the inspection of facilities subject to approval under the German Federal Pollution Control Act (*Bundesimmissionsschutzgesetz*). "Whole-plant inspection" means a comprehensive system inspection and monitoring of a plant with regard to safety functions.

This procedure takes in material properties, process conditions, interaction between apparatus and other plant components, interaction between human beings and hardware, administrative policies, and the effect of external safety-relevant factors. Inspections in such a program are concerned with whether the operation complies with legislative requirements (pollution control, occupational safety and health, water quality, soil conservation), pertinent regulations, and recommendations.

These inspection and surveillance tasks concern all those concerned. The three pillars of whole-plant inspection are thus:

1) Supervision of the plant as part of the operator's responsibility
2) Inspection and surveillance by public agencies

3) Safety inspections by experts

Such a procedure can also serve as a model for the inspection of plants, as proposed in a draft European Council Directive for avoiding the dangerous consequences of serious accidents with hazardous substances.

4.4. Maintenance

A plant operating in a trouble-free manner is in its safest condition. However, because technical components are subject to mechanical and process-related wear, upsets can occur. As a result, maintenance is necessary to keep the plant in a safe condition or restore it to such a condition. On the other hand, maintenance can create new dangers in the plant.

This maintenance-related risk can be minimized only by good safety practices in the planning and execution of maintenance work.

In the past, mistakes in the preparation or execution of maintenance were a significant cause of accidents in the chemical industry. The gas explosion at Flixborough in 1974 was traced back to a makeshift repair procedure [218], and many smaller and less spectacular events have resulted from maintenance errors [219], [220]. In a representative time interval, 30 % of all events occurred during maintenance [220].

Therefore, the value of safe maintenance in the chemical industry cannot be overstated. This is not surprising if the cost of maintenance is analyzed. It amounts to 3 – 5 % of the plant replacement value per year; in large companies, this can add up to more than DM 10^9 a year [221], [222]. These costs arise from a large number of small operations, and are made up mainly of personnel costs (including those incurred by vendors). A high level of administrative and logistical expenditure is called for. Maintenance actions, especially repair work, are only partially recurrent; many repair jobs must be planned and carried out individually.

These points imply the following three fundamental goals:

1) Plants should be designed and constructed in such a way that they are easy to maintain, i.e., easy to repair (good cleaning and draining capabilities, proper access, etc.); require little maintenance; and are made up of the most reliable and long-lived components possible
2) The proportion of unforeseen repairs caused by damage should be reduced in favor of scheduled (including preventive) operations
3) Safe procedures must be adopted and enforced for the performance of maintenance work, to reduce the risk arising from maintenance

4.4.1. Actions During Plant Design and Construction

The task ensuring safety during maintenance work is to create the technical and administrative conditions for safe performance of the work. This requires a systematic procedure (Fig. 61).

A good maintenance strategy begins with the design of a low-maintenance, easy-to-maintain plant. Every intervention in the plant can lead to danger during maintenance work and on restarting. The achievement of long life and high reliability at this stage is also economically important.

Systematic safety analysis (e.g., HAZOP) can identify the consequences of malfunctions and their possible causes at the design stage. Two types of event must be distinguished:

– Events that follow immediately from the technical failure and the resulting deviation of the process parameters from the design conditions
– Events that can occur during a maintenance operation

The objective in event analysis is to minimize hazards:

– To achieve the highest possible reliability in terms of failures, and to limit the consequences of failures
– To minimize the repair risk, i.e., to reduce the number of maintenance actions and to perform them as safe as possible

Selection Criteria for Apparatus and Machinery. High reliability is obtained by designing and selecting components on the basis of their requirements. Key criteria are:

Construction materials

Figure 61. Maintenance strategy: central significance in a chemical plant

Functional principle
Robustness

Secondary points are hardware safeguards against improper operating conditions, e.g., flow monitors on pumps, which help to prevent damage.

Because a component may fail anyway, the consequence of such a failure must be analyzed. Even if the probability of occurrence is low, an event (failure mode) with serious consequences can influence the above criteria and make it necessary to seek a different solution.

Once these criteria are set, quality assurance systems must be instituted to monitor and guarantee compliance with the standards during the subsequent fabrication and installation of apparatus and machinery.

Design Criteria. Because maintenance and repair are inevitable, danger arising from them can be most effectively minimized by good installation and design practices. The criteria at this stage include clear layout (accessibility), easy and safe disassembly, and draining and pressure-relief capabilities. In a chemical plant, special importance attaches to draining. Some maintenance jobs can be made safer by the use of assembly aids, local spot-vent systems, etc.

Aids for Monitoring Plants and Performing Safe Maintenance. The documents needed for reliable operation and safe maintenance should be created at the design stage. These documents can usually be assembled from documents required for plant design and construction, e.g., manufacturers' data sheets, internal experience reports, and piping and instrumentation diagrams.

Periodic inspections are supported by maintenance and inspection schedules, which must be present when the plant is commissioned. Test methods involving no opening of equipment or piping in the plant (e.g., ultrasonic inspection) are preferred. Where safety-relevant process control equipment is not redundant, self-

monitoring is recommended. Inspections, including functional tests and plausibility checks, help todiscover concealed defects and to identify needed repairs. In some situations, automatic monitoring devices such as vibration monitors can also be used.

Anticipated, i.e., recurrent repairs must be thought out ahead of time. Detailed job instructions, supported by extracts from technical drawings (job cards, Figs. 62, 63), cut the number of mistakes during a repair or preparation for one.

Other documents needed later for the proper execution of maintenance tasks include: piping and instrumentation diagrams with piping and seal specifications; piping and fitting lists; apparatus specifications; measurement station data sheets (to ensure compliance with standards); and functional diagrams of the process control system with lists of setpoints, limits, and alarm settings (unambiguous transfer of process parameters to process control system).

4.4.2. Actions During Plant Operation

Figure 64 illustrates the maintenance strategy for this phase. The maintenance task is to keep the plant in its nominal condition so that requirements on product quality, safety, and availability are always met. According to DIN 31 051, maintenance is defined in the following way:

1) Preventive maintenance: monitoring and keeping plant in nominal state
2) Inspection: determination and assessment of actual state
3) Repair: restoration of nominal state

There is a fundamental distinction between scheduled maintenance and breakdown maintenance. An attempt is made to minimize the proportion of breakdown maintenance caused by unforeseen failures. Scheduled maintenance is particularly concerned with components having safety and quality relevance; it includes upkeep and inspection as well as measures to obviate repairs or cut their cost [223], [224].

Preventive maintenance and inspection are usually done according to predetermined schedules and are thus systematic (timing and scope set in advance). Maintenance and inspection schedules are used for this purpose. Inspections are scheduled on the basis of the anticipated wear of the components involved, known either from manufacturers' data or from operating experience.

Preventive maintenance and inspection are done both while the plant is on stream, nominal/actual comparisons being made continuously and documented during regular rounds, and during scheduled shutdowns. Maintenance and inspection schedules are a reliable and efficient way to organize the latter. Unforeseen failures of plant equipment occur despite scheduled maintenance, and these must be covered by administrative policies (usually operating procedures) providing for later repairs. This "breakdown" maintenance is also supported by repair instructions and aids rendering the work more reliable and faster.

4.4.2.1. Maintenance Activity

The procedures for scheduled and breakdown maintenance are similar (Fig. 64). The key step in minimizing risk of breakdown is early detection of a deviation from nominal conditions, which can be apparent in:

– Obvious defects: drips, noise, etc.
– Concealed defects, e.g., gradual slippage of process parameters

Regular rounds by shift personnel under a fixed plan can aid detection of the problem and thus contribute to minimizing risks. The maintenance and inspection schedule for every technical component contains information on:

– Test criteria applied in maintenance and inspection
– Methods practiced
– Timing

The action ends with a finding, documented in a report signed by the inspector.

If problems are identified, but cannot be remedied immediately, they are recorded in the plant shift log. The description should be oriented to the concrete observation, and should not contain speculation about the cause. The proper remedy cannot be established until the malfunction or the damage has been jointly assessed by plant management, the shift supervisor, the shop supervisor, and in some cases a specialist. A meeting must be held to determine how and with

what precautions the repair work is performed (Section 4.2.2.2).

A further aid to proper reporting of technical problems by operating personnel to maintenance personnel is the technical shift log, which simultaneously serves as a tool for evaluating damage; the shift personnel enter the following information:

– Trouble during the shift
– Exact location (i.e., identification of component)
– Nature of trouble or malfunction observed
– Time of discovery

The log should also show what maintenance action was taken; the person responsible must sign it.

The purpose of the technical shift log is to state clearly what was done, and who was responsible, to prevent ill- considered and uncoordinated repair efforts. With the help of the technical shift log – including the signature of the responsible person – it is always possible to verify that necessary action has been done properly.

The technical shift log performs two other functions:

– Identification of temporary and makeshift repairs
– Evaluation in terms of recurrent problems (analysis of weak points)
– Computer support is recommended so that:
– Temporary repairs are not left in place permanently
– Statistical analysis can be done and appropriate countermeasures instituted to extend service life and reduce risk by cutting the number of repair projects [225]

Safety procedures must be followed whether the maintenance job is:

– Anticipated when preventive maintenance, inspection, and repairs are to be carried out during a scheduled shut-down (scheduled maintenance); or
– Unplanned, i.e., caused by a failure (breakdown maintenance)

In either case, the procedures must be designed to cope with the risks occurring at every stage.

If a problem arises, e.g., failure of a safety device, it may directly affect plant safety. This aspect is not pursued here; the proper response is always set out in the context of the safety analysis.

As a rule, the plant or sections of it must be put in a safe condition by a shut-down procedure when a problem occurs; this must not be confused with the "emergency off" or "panic" button for a section of the plant. While planned or "checklist" shutdown of the plant is a frequent procedure, the failure of a technical component required for shutdown may lead to the isolation of specific apparatus or sections of the plant, or to overriding the safety interlocks. Examples include bypassing a leaking agitated vessel and releasing an interlocked fitting that normally cannot be opened except at a certain point in the reaction.

Shutdown is not always necessary. In many instances, countermeasures can be taken that do not lead directly to a solution of the problem. There are three possibilities:

1) Postponing the proper repair (e.g., temporary plugging of leaks)
2) Using planned fallbacks (e.g., putting standby systems on stream)
3) Taking alternative measures (e.g., blowing a vessel down instead of pumping it dry)

Alternative actions are temporary modifications; such makeshifts may be more desirable than immediate shutdown of the plant, e.g., in a large continuous process where operation can be maintained until the next planned shutdown. Any modification must be checked first by a systematic safety analysis.

4.4.2.2. Performance of Maintenance

Scheduled and breakdown maintenance differ, especially in the documentation existing at the start of production, which describes the specific work to be done and takes the form of instructions:

– Scheduled maintenance is covered by preventive maintenance and inspection schedules describing the nature and scope of the work. Repair instructions (e.g., job cards) are generally used. Plans for shutdown maintenance are of this type, especially in continuous process plants.
– For breakdown maintenance, the problem and the corrective action taken are recorded in the technical shift log. Special repair instructions are not always available, and the documentation is then limited to the written plant documentation, including updates.

There are essentially two further possibilities:

1) Maintenance work while the plant is on stream
2) Maintenance work during a shutdown

In what follows, only maintenance during shutdown is discussed. There is no fundamental difference between total and partial shutdown. The only routine actions that should be taken in an operating plant are those that raise no safety concerns.

Maintenance can be broken down into three phases:

Preparation
Execution
Post- completion measures

When danger can arise during the performance of this work, all workers involved must follow special safety practices, which are written up in a "work permit". The purpose of this is twofold: to make certain that the proper safety procedures are followed; and to ensure that responsibility for the components of the work are clearly defined by signature.

Work Permit **No.**

Equipment: **Polymerization reactor 1 (R 3.02)**

Description of work (incl. to whom assigned)
Reattachment of submerged product feed pipe by fitters

1. **Isolation of plant section/component:**
   Depressurize all product lines connected; open pipe unions and close off with blank flanges; disconnect N_2 lines and close off with blank flanges. Disconnect external steam tracing. Disconnect power to agitator motor. Release interlock on bottom drain valve. Completely empty vessel through R 2.03, and leave valve open.
2. **Actions on isolated plant section/component:**
   Using high-pressure cleaning unit, clean vessel with water through manhole. Close bottom drain valve and fill with water. Drain both cleaning waters through R 2.04 for analysis. Have specialist team perform radiometric measurement of level from outside pipes. Suspend ventilation device in vessel. Close bottom drain valve.
   Date: Time: Signature:
3. **Action before beginning work:**
   Instruct fitters that no welding or driving is permitted.
   Instructions given to: Signature:
4. **Occupational safety measures:**
   Introduce conductors safely into tank; post lookout at manhole; ventilation unit; protective clothing for fitters in vessel; only ordinary work clothing (note: hardhat, protective goggles, safety shoes, . . .).
5. **Actions after completion of work:**
6. **Management approval (by plant manager) for performance of work:**
   From 1 March 1993, 10 : 30 am, to 1 March 1993, 4 : 30 pm
   Date: Time: Signature:
7. **Signature of shop supervisor responsible for compliance with items 4 and 5**
   Date: Time: Signature:
8. **Approval to proceed on site by engineering supervisor of plant**
   Date: Time: Signature:
9. **After completion of work: approval by plant supervisor**
10. **All- clear and technical acceptance**
    All clear:
    Date: Time: Signature of shop supervisor:
    Technical acceptance:
    Date: Time Signature:
11. **Waiver of stated procedures (see 1 and 2)**
12. **Acceptance before restart**

Preparatory steps include isolating single components or whole sections of the plant. This requires proper shutdown of the section concerned to a safe condition. Where redundant components exist for the malfunctioning components, plant management and/or the set operating instructions may allow these to be placed on stream. Other temporary actions such as:

– Blowing down instead of pumping dry
– Changing the preset process control switching or alarm values
– Interfering with interlocks

are permitted only after a special safety check, unless they are provided for in special operating procedures.

After shutdown, the critical danger points are release of substances by opening up the system to drain it (danger of poisoning or fire/explosion), and the possible introduction of undesired substances during cleaning.

Ideally, a plant should have emptying devices and holding tanks for the contents of the equipment, so the plant does not have to be opened for drainage. This concept is desirable for substances with high hazard potentials, but the cost may be substantial. Regardless of whether fixed holding tanks are installed, emptying by gravity should be possible.

Normally it is necessary to drain only certain portions of the plant. Such areas can be safely separated from other, product- containing sections by closing some fittings and inserting blanks. Residual quantities of product remain in the drained parts of the plant, however, especially in fittings, filters, and pumps. The individual draining features of these must be used to free them of product. Drainage is frequently aided by nitrogen pressure. Subsequent cleaning is not required with highly volatile substances. The vented air from such an operation must be considered; a vent system may be necessary, along with downstream treatment of the gases.

When cleaning is required, the agents used must be compatible with the product and, physiologically, as innocuous as possible. If inert media cannot be used, the following become particularly important:

– Medium adequately diluted in the shortest possible time

– Agent reactive only with the small quantity of product found in the drained segment of the plant
– Cleaning liquid safely separated from sections of the plant containing larger amounts of product

Failure to observe these conditions has frequently led to events, often because, in a nonroutine cleaning operation, the flow direction, pressure, and valve configuration were different from the normal conditions, and so were interpreted wrongly. All connections to other sections of the plant must therefore be examined, including those not ordinarily filled with product (e.g., off-gas piping).

When maintenance work calls for disconnection or disassembly of a plant section, personal injury hazards can arise if the repair site is not rendered safe, e.g., if the electric power to drives is not disconnected or product-filled pipes are not safely closed with a blank flange after disassembly of a subsystem. The latter point is crucial when equipment such as pumps and fittings are disassembled, because the safety measures are carried out right at the disassembly site; in larger maintenance operations, entire piping systems are generally made product-free.

Engineering codes, accident prevention regulations, and special safety instructions aid in the proper execution of these operations. To avoid misunderstandings at the site, particularly in a complex installation, the defective item must be identified, and its isolation must be indicated visually. The area can be further marked with a tag stating which craft has jurisdiction and what kind of work is being done.

The key requirement for safe repairs is up-to-date plant documentation. On the basis of the technical specifications (complete and unambiguous description of performance data, media, construction materials, and design data), it must be ensured that parts and materials used (e.g., greases) are such that no danger arises when the affected part of the plant is on stream.

Hazards in this sense are leaks due to improper materials (e.g., gaskets) or incorrect temperature/pressure design; unwanted reactions due to the catalytic action of construction materials or other media present; and parameters outside safe ranges owing due to the installation of unsuitable equipment (e.g., a pump with too large an impeller generating an excessive pressure). Similar hazards must be considered when replacing or repairing process control system components. A typical mistake involving an instrument is the use of the wrong range.

Just as a repair or inspection site must be labeled to prevent confusion, replacement parts or newly delivered repaired components must be labeled so they can be recognized as equipment meeting the specifications. Often there is no outward difference between two parts, e.g., when only the materials inside the device differ.

These practices are intended to ensure that the on-site activity can be finished in the shortest possible time, without interruption or risk. Safety and economy are not in conflict.

Virtually every maintenance activity comprises many single activities performed by different crafts. Because economics does not permit craft specialists to be employed especially for all such tasks, workers unfamiliar with the special hazards of the production plant have to be brought in; the requirement of up-to-date plant documentation must be supplemented by explicit instructions to the craftspeople at the work site, and a clear task description (see the job card in Fig. 62).

It is necessary to establish both the plant documentation needed for maintenance, and the scheduling of various maintenance activities in a plant area. Only by matching and skillfully coordinating maintenance activities to the rhythm of the process they can be prevented from threatening each other. An aid in this respect is a working plan, which describes the sequence of tasks and their duration from their starting times (e.g., a bar chart). In an area where welding, driving, and caulking work is done, for example, explosive mixtures are not permitted. Production not connected to the maintenance action may have to be interrupted. The same holds when flammable or explosive substances are present in the course of maintenance, e.g., when a protective coating is applied to a surface.

Some kinds of work also require a second person to be present, even if the job requires only one craft worker. This is the case when a hazard such as the escape of toxic or explosive mixtures cannot be positively ruled out, or when work has to be done inside vessels.

Maintenance jobs can extend over more than a day, so interruptions cannot always be avoided.

The area of the plant where repairs are being done should be marked off with signs throughout the job, especially to prevent an inadvertent return to service before the work is complete.

Approval to restart can be given only by persons whose functions include this task, e.g., the responsible plant engineer. Only a single person should be made responsible for maintenance. This person is the contact point throughout maintenance, otherwise there is a danger that someone who does not have an overview of the work may make a wrong decision.

To avoid the danger of premature startup, interruptions of the work must be recorded, e.g., in an attendance log, and completion must be documented in the technical shift log. For work that requires a permit, the permit includes a space for approval after completion of the job.

A maintenance action cannot be considered finished until all the unit activities have been checked and accepted by the coordinator of the overall action. This includes both inspection for correct execution of a task, and functional testing. Proper execution means both the use of the components provided (correct temperature and pressure ratings, material, etc.) and their functionally correct installation. Functional testing is then done to make certain that all technical components work together in the way necessary for the process. The simplest example is leak testing of a repaired section of the plant; a very complicated one is the comprehensive testing of a process control system.

Where preparatory action has been taken, e.g., isolation of sections of the plant, these must be reversed in the same way as temporary modifications. Approval can then be given for production. In some cases, the plant is restarted a step at a time, extra functional tests with reduced throughput or enlarged crew being done first. Such precautions are needed especially when extensive maintenance work has been carried out.

4.4.3. Continuing Plant Development (Analysis of Weak Points)

The elimination of problems by repair is a necessity, but it also offers the plant operators a chance to analyze recurring problems, and to use the results in improving the system. Analysis of maintenance actions for continuing development presupposes that the technology and the operating conditions are adequately documented (this includes unambiguous nomenclature in the plant). Entries in the technical shift log aid in evaluating the frequency of problems. If plant documentation is computerized, the cost of such a "weak point analysis" can be substantially reduced. The goal is to use technically feasible and economically acceptable means to optimize sections of the plant, i.e., to minimize the frequency and/or severity of trouble. Before such an analysis, the possibility of human error causing the problem must be eliminated.

This analysis of weak points must not be limited to the technology. Often, the technical defect can be eliminated more simply by changing the process conditions. The weak point found may not be the cause, but rather the effect, of defects in the process, e.g., process conditions or product specifications. In such cases, the analysis of weak points becomes a process analysis (Section 4.5).

The causes of problems may well be hard to identify. A final statement of causes often has to be based on the vigilance of the operating personnel on the spot, as well as the years they have spent learning the details. The plant manager must therefore make a continuing effort to motivate the personnel to be observant.

4.5. Modification of Plants

4.5.1. Reasons for Modifications

While the objective of maintenance is to keep the plant in its nominal condition, modifications to the process and plant involve changing the documented nominal state of either, or both. A variety of factors can lead to process and plant modifications:

- Increases in capacity
- Change in process to lower manufacturing costs and/or improve product quality, or to modify the product
- Measures to eradicate weak points
- Upgrading to the state of the art (technology or safety)

Any change in the nominal state means that the corresponding parts of the process and plant documentation must be revised or rewritten.

In this respect, modification differs in scope, but not in basic execution, from a new design project. The reason it is so important to treat a modification like a new design is that there is no way to know ahead of time how widely the modification will ramify itself. Even minor changes, e.g., replacing one apparatus by another, or raising the temperature in a unit operation, can cause a violation of the design or process control parameters. The systematic methods already described for evaluating new plants must be applied here too, because they cover the entire field of possible hazards. First, all areas of concern, e.g., explosion hazards, are studied to determine whether the proposed change affects them at all. Because a change often relates to only a few danger spots, the number of areas of concern quickly becomes small, as does the number of aspects to be considered; detailed analysis is needed for only a few aspects in most cases. Knowledge of the existing safety concept is essential for assessment of all new practices. Any change represents a "compatible" expansion of the whole concept.

4.5.2. Procedure for Modification

A suitable procedure must be established if modifications are to be carried out correctly. As soon as a major change becomes necessary in the plant, e.g., because a new unit operation is being introduced, the project is implemented in the same way as any other design project, right up to the construction of a new plant (Section 3.2).

In the case of minor changes, the amount of investigative effort required is generally small, so a simplified procedure is useful in such cases. The principle remains the same, but the effort invested in safety analysis and documentation updating is matched to the scope of the planned change. A useful aid is the change sheet, which has two functions: to describe the objective and the implementation of the planned change; and to insure that necessary safety questions have been asked and properly answered. The change sheet also documents the work and its approval, and is used in identifying the parts of the plant documentation affected by the change (Section 4.4.1). A signature is required for each approval and each inspection of each individual step in the process. The work permit already mentioned complements this task by listing actions to be taken during its execution.

The items contained in the change sheet are:

1) Identification of what is to be changed (including nature of change and other ordering criteria; suitable tools for this purpose are job cards, piping and instrumentation diagrams, and operating manuals)
2) Purpose of the change
3) Description of the change
4) Identification of essential danger spots with the help of a checklist
5) Discussion with specialist departments on the danger spots relevant to each
6) Inquiry into necessary updating of safety analysis
7) List of plant and process documents affected, with possibility of monitoring progress of the change; testing steps after completion (e.g., acceptance test, test run)
8) Questions as to possible effects on product quality

Important consultations with the specialist departments and other safety information must be recorded, and the safety analysis must be attached.

The following fictitious examples show how small changes can have wide-ranging consequences.

1) An additive used in a thermally sensitive mixture is purchased from another vendor; the composition appears to be only slightly different, but it lowers the safe temperature limit. The mixture is to be subjected to distillation at high temperature. The result is thermal decomposition of the bottoms, faster heat evolution, and a rise in pressure in the reboiler.

Corrective action: Perform safety study in the lab with the new feedstocks; lower the temperature set point.

1) A pump delivering acid from a storage tank must fill a vessel more rapidly. On the basis of the characteristic curve, the old pump was selected so that the vent line of the vessel cannot be completely flooded. As a result, releases of substances are prevented without a level-limiting feature having to be installed. The new pump, with a larger impeller, attains a higher pressure. It is now possible to flood

the vent completely so that acid is released. The danger is not noticed as long as overfilling does not occur. The inherent safety formerly present no longer exists.

Corrective action: Select pump according to proper safety documentation; see change sheet.

4.5.3. Summary of Plant Maintenance and Process Modification

The systematic procedure described, with the associated aids, contributes to plant safety from design to operation and process upgrades. By itself, however, it is not sufficient to guarantee plant safety. While it cannot replace the knowledge of experienced workers, it offers a guide and support for daily work. The reasons for the increasing volume of technical documentation and administrative support are:

– Plants themselves have become far more complex (process control engineering and other advances)
– Maintenance work is being done by a larger number of specialized teams
– There is increased public interest in readily understandable safety practices

5. Hazard Control

5.1. Means of Limiting Accident Impacts

The responsible care of every plant-operating company to take active measures to protect employees, third parties, and the environment against potential harm means that the operator must take responsibility for technical and administrative precautions to limit the impacts of minor and major accidents in the facility. Legal and regulatory provisions independently require limitation of the consequences of accidents in plants; e.g., the "Seveso Directive" [226], [227] and the implementing regulations in EC member countries.

Action to limit accident impacts is also mandated by other regulations, e.g., the German Pressure Regulation [228]. The release of substances from pressure-relief features of a plant (safety valves, rupture disks, emergency blowdown devices) must present "no hazard" to employees, third parties, and the environment [228], [229].

Whether such a release is permissible must be assessed in view of the properties of the substances, the location of the plant, the propagation behavior of the substances, the duration of the release, and the occurrence of hazardous concentrations. If a release is not possible without hazard, retention or disposal equipment must be provided to limit the consequences.

German water law also requires that plants be designed, built, and operated in such a way that water pollutants cannot escape. Substances that escape anyway must be retained quickly and reliably so that contamination of receiving waters does not become a concern [230], [231].

The basic idea of a two-barrier system is contained in these provisions. The enclosing shell of a storage tank, e.g., for fuel oil, or the pressure-resistant construction of a reactor in the chemical industry, is the first barrier; it must safely withstand the mechanical, thermal, and chemical stresses imposed on it in normal operation, and in the event of accidents.

If a release occurs in spite of the preventive measures, a second barrier must limit the consequences of the release in such a way that employees and third parties, as well as the neighborhood of the plant and the environment, cannot be threatened, or that such threat is held to an acceptable level.

The chemical industry uses a variety of means to limit the impacts of accidents. As a rule, these also have functions relating to occupational safety, pollution control, and water and soil conservation. In addition to retaining the product in liquid, solid, or gaseous form in case of an upset in the plant, they also provide for retention of contaminated wastewater or cooling water, and the retention of water contaminated by fire fighting.

The necessity of retention systems and the way in which they are implemented depends chiefly on the properties of the substances being handled, or those produced in the plant during an accident, and on the actions of such substances on persons and the environment – not just in terms of the immediate effect of exposure, but also the effects produced by a reaction (fire, explosion) of such substances. The hazard

potential of a substance is assessed on the basis of its physical, chemical, and biological properties. The water-polluting effect of a substance is generally evaluated from its assignment to a pollutant class [232], [233], based on the acute toxicity of the substance to mammals, bacteria, and fish (sometimes to algae and Daphnia), its degradability, long-term effects, and distribution.

The principal ways to limit the impacts of potential accidents are:

– Retention systems, catch wells
– Quick-closing valves, emergency compartmentalization systems
– Emergency drain and collection systems
– Blowoff and disposal systems
– Spray-curtain systems
– Partial and complete containment
– Fire protection
– Retention of water contaminated by fire fighting

The choice of the means to limit accident consequences must be based on the operating conditions (e.g., pressure, temperature, substance properties), the type of plant, its location, and the situation in its vicinity.

5.1.1. Retention Systems, Catch Wells

The best-known retention system for liquids is the catch pan or well. In Germany, the Engineering Code for Flammable Liquids (TRbF) prescribes this way of retaining any liquid that leaks from tanks located in the well [234], [235].

Catch wells not only prevent harm to soils and receiving waters by flammable liquids, but also limit the spread of fires and emissions. If the liquid surface is completely covered (e.g., with a low-expansion fire-fighting foam), fires and emissions can be almost entirely suppressed.

In addition to product retention, a catch pan or well can also hold back contaminated wastewater and water contaminated by fire fighting.

Special requirements apply to the design and selection of material of chemically resistant, leakproof retention systems such as catch wells, pans, and baseplates. These standards are chiefly dictated by the stresses occurring, for example:

– Mechanical stress due to loads, impacts, friction, building subsidence, internal stresses, and contraction
– Thermal stresses due to ambient temperature cycles (day – night, summer – winter) or hot media
– Chemical stresses dependent on water pollutant class, intermittent attack, penetration, or aggressive properties of retained substances relative to construction materials

The resistance to chemical attack needed in a retention system, and hence the material chosen, generally depend on the water pollutant classification and chemical nature of the substances present. Chemical stresses are classed by severity:

1) Low load: no water pollutants present in normal operation; retention of water contaminated by fire fighting
2) Moderate load: leaks with action limited in time (nonrecurring or recurring but brief)
3) High load: intermittent contact with water-polluting liquids; regular contact with heavily laden cleaning water

The duration of exposure must be determined for each component. If the loads are low or moderate, the design can be based on a fairly low-probability event, occurring once and of limited duration. Infrastructural administrative or technical measures, e.g., provision for prompt detection and remedy of leaks, may also be taken [236–239].

If required by the load assessment, retention systems can be rendered tight and chemically resistant by special coatings (resins, paints, etc.) or plastic or metal foil liners.

A large industrial plant can set up a further barrier for retention of chemicals and contaminated fire-fighting water by connecting production equipment or storage tanks to biosewers leading to the plant's wastewater treatment system.

A special type of retention system involves double-wall construction of vessels, pipes, etc. The retention space is attached to the containing barrier (in the case of internally jacketed vessels, placed inside it) in such a way that the space between the two walls catches any leaks and can be fitted with an alarm [239–242].

Double-wall design is not always safer than single-wall construction. The reasons have to do with fabrication cost and additional stresses

(e.g., those due to constrained expansion at penetrations and supports) as well as stability against denting and buckling. Inspection and maintenance of a double-wall component is difficult or impossible.

5.1.2. Rapid-Closing Valves, Emergency Compartmentalization Systems

In plants containing large amounts of products where the release of a substance would represent a high hazard potential, it may be useful to subdivide the plant with rapid- closing valves and fittings. These can be actuated after the detection of a release, e.g., by a gas warning system [243], [244], and after the scope of the release has been evaluated. They can be activated manually or automatically. The effect is to isolate the area of the leak from the rest of the facility. The quantity released at a leak can thus be limited to a value estimated in advance. The use of a rapid- closing valve system presupposes detailed advance planning and design of the plant sections, knowledge of the amounts of products contained, the way in which a leak is detected, etc. The analysis may also include the emergency shut-down of the entire plant if dangerous conditions in the plant can be created by blocking individual sections [245], [246].

5.1.3. Emergency Drain and Collection Systems

The product in a plant or in an isolated portion of the plant may be drained or released into a retention system (e.g., a catch tank or blowdown tank permanently installed in the plant) if a leak or other hazardous condition arises (e.g., fire). The retention system may be fitted with a separator (e.g., a cyclone) if the properties of the substance and the system pressure demand separation of the phases of the substance. It is also useful to configure the system in such a way that the plant drains by gravity. A pressure-relief system may also be needed to reduce the pressure of the gas phase [247], [248].

5.1.4. Blowoff and Disposal Systems

In plants handling gases, flares, scrubbers, absorbers, and condensers are useful for pressure relief and gas disposal. Systems of this type function not only as emergency pressure-relief systems, but are also used for the disposal of gases and vapors arising during normal operation, or when the plant is up or shut down, e.g., where large amounts of low-quality gas are produced for a short time. If these gases or vapors are flammable, the plant design must also meet the safety standards for explosion protection; other safeguards against spontaneous ignition and fire may also be necessary, e.g., with absorption on activated- carbon filters [249], [250].

5.1.5. Spray-Curtain (Drench) Systems

Spray curtains are often employed in plants with critical gases or vapors, where a release at an unpredictable location cannot be ruled out and may lead to a hazard to employees, third parties, or the environment. The plant section in question, or the whole plant, is surrounded by a pipe system fitted with closely spaced spray nozzles. If a pollutant escapes, a high-pressure mixture of water and steam issues from the nozzles, surrounding the plant in a dense water mist that can condense or capture the released substances. Neutralizing agents can also be added to the water; e.g., ammonia for phosgene plants. Due to the high-pressure and thermodynamic effects the effectiveness of these systems can be maintained, even in windy weather.

Mobile equipment such as articulated booms and water cannons operated by the plant fire fighting service can be used to create spray curtains in smaller plants, or as a supplementary measure in larger ones [251].

5.1.6. Partial and Complete Containment

A technique well known from the nuclear industry is to place the entire plant inside a pressure-tight containment, enclosed on all sides, but with personnel entry points. This approach has also been discussed for chemical plants and portions of plants where very dangerous substances are handled.

This approach may be correct from the environmental protection standpoint, but in practice there are limits, since some chemical plants

cannot be remotely controlled and cannot be run without operating personnel.

For reasons of occupational safety and health, a chemical plant containment cannot be hermetically sealed from the outside world while the plant is in normal operation. Entry for operation and maintenance must be possible, and continuous ventilation is required, both for waste heat removal and on occupational health grounds. A release would have to be detected very promptly in order for all openings to be shut and the stack-gas cleanup system turned on so that retention could be achieved.

A further problem arises with flammable substances. Even a small cloud of an explosive mixture released because of a malfunction is diluted much more slowly in the containment than in an open plant, so it remains flammable over a long time. Containment also exacerbates the effect of an explosion; because there are no pressure-relief openings, the pressure wave and heat of an explosion affect humans and structures many times more than in the open case.

A large fire in a containment plant inevitably causes a huge amount of heat to accumulate in the building. Thermal stresses on the structure and plant equipment result, possibly causing their complete failure. Mobile fire fighting is far more difficult in such a facility.

It is possible that an initially minor event in a containment plant may lead to substantial personal injury and a dangerous release of substances.

A variety of plant subdivisions, where special process or design conditions bring about a severe hazard potential for the environment, are already being built with double walls or enclosed in boxes or compartments. Aside from this form of enclosure and double-walled construction, whole-plant containment cannot be recommended for general use. Complete containment is an option only in rare cases, e.g., where there are no flammable or explosive substances; even in such cases it is necessary to strike a careful balance between advantages and disadvantages (pollution control, industrial safety, fire and explosion protection, plant reliability, and safe maintenance practices) [251–253].

5.1.7. Fire Protection; Retention of Water Contaminated by Fire Fighting

Effects on employees, third parties, and the environment must also be expected when fire occurs in the plant. These can result from the fire itself (heat, combustion gases, etc.), or from the extinguishing agents (e.g., the Sandoz accident at Basel). Fire protection legislation requires that the fire fighting service seek to extinguish a fire virtually always and under all circumstances. From the environmental protection standpoint, it may be preferable not to extinguish a fire that has already passed a certain size, but to let it burn at a high temperature while keeping it from spreading to the surroundings; the amount of environmentally harmful combustion gases generated is smaller, and no contaminated extinguishing agent is produced.

There must, however, always be fire protection measures to prevent the start and growth of a fire, or to safeguard the surroundings from the effects of fire (Section 3.4.1). Fixed facilities for the retention of water contaminated by fire fighting must be provided, depending on the substances involved, their water pollution classifications, the construction of the first barrier, and other factors [254].

Mobile retention systems can also be used as a barrier. A number of options, e.g., mobile folding vessels and rapid-set-up tanks, are now on the market. Even simple devices such as magnetic plates and compressed-air bags to close off sewer intakes, have their place in contaminated fire-fighting water retention.

5.2. Hazard Control Plans at Plant Level and Beyond

5.2.1. Hazard Control Plans

In what follows, plans established by a plant or works to control hazards inside the battery limits are referred to as plant alarm and hazard control plans. In Europe, plants subject to the "Seveso Directive" (implemented in Germany as the Industrial Emergencies Regulation) are required to create an alarm and hazard control plan [255], [256].

An alarm and hazard control plan describes administrative and technical actions to minimize the impacts of accidents; relates to various levels

of organization (e.g., constituent plants and the larger facility to which they belong) and is prepared with an eye to the immediate surroundings of each unit.

The actions prescribed include:

Management
Personnel
Technical resources
Communications
Documentation
Procedures and jurisdictions

In facilities containing a large number of varied units, alarm and hazard control plans are prepared at "plant" (smaller unit) and "works" (larger unit) levels [257].

5.2.1.1. Plant Hazard Control Plan

The plant alarm and hazard control plan sets forth the plant safety organization. It contains information necessary to plan and specify the emergency response.

The coordinated administrative measures taken in response to an accident are such as to afford the highest possible level of protection to humans and facilities.

The hazard control plan identifies all potential threats within the plant (e.g., those due to fire, explosion, or other accident) and external to the plant (e.g., trouble in nearby plants, flooding), lists safety equipment in the plant, and prescribes the desired actions of plant personnel in a dangerous situation.

The plant hazard control plan is aimed primarily at the people in charge (e.g., plant managers and engineers, laboratory and workshop managers), who must ensure that their personnel are properly instructed as to how to act in a particular hazard situation. The plan is a document for use in plant personnel instruction and drills, as provided in the Industrial Emergencies Regulation. The plant hazard control plan serves as a guide for people in charge, giving instructions for actions in a particular hazard situation. It lays down guidelines both for measure within the plant and for measures by technical task forces and service groups (e.g., fire safety, occupational safety, plant security, maintenance). The plan is also an informational aid and guide to emergency action for management, and provides a pattern for the allocation of technical resources.

5.2.1.2. Works Hazard Control Plan

The alarm and hazard control plan of the works relates to a higher organizational level than the plant, and documents the emergency response organization adopted by the works when an event occurs.

It defines, for all personnel involved:

The essential tasks to be performed
The way in which efforts are coordinated

It also establishes duties relating to information and prescribes the forms of cooperation with:

External organizations
Government agencies

5.2.1.3. Required Contents of the Plan

Many suggestions have appeared concerning what alarm and hazard control plans should contain [258], [259]. In the German state of North Rhine – Westphalia, a working group, including independent experts as well as agency and industry representatives, has developed a model plant alarm and hazard control plan [257], which can serve as a pattern for plant or works plans. Major headings in the model plan are:

Introduction. Mailing address, scope, revision (update) status

General Information on the Facility and its Surroundings. Orientation for emergency workers on:

1) Access routes and staging areas
2) Information on the work force
3) Danger sources, major hazards
4) Safety equipment and plans in place

Alarm Plan. The routing of alarms in the event of an accident is summarized, as is mandatory internal and external reporting.

Hazard Control by Internal Activities. This lists departments in the works (works manager, plant, works fire service, central safety office, industrial medicine, safety engineer, etc.) and defines their jurisdictions and assignments.

Warnings. Options for informing persons in the works or plant about possible hazards are discussed, along with ways of delivering warnings and other information to those living nearby.

Instructions for Particular Events. In view of local circumstances, precautions and responses are described for a variety of events (flood, smog, power outage, product release, need for outside assistance, etc.).

Notification of Government Agencies and the Public. This describes the internal location, where all information required to be reported externally can be retrieved.

Resources and Technical Specialists. A table lists all current technical documents, devices, equipment, and technical specialists, and records their availability and contact information.

Telephone List. Telephone numbers that may be vital for government agencies (for inquiries within the works) and for responsible works management personnel (e.g., for reports to agencies) must be listed here.

Definitions, Regulations, Conventions. This lists concepts and procedures defined in regulatory documents; key passages may be quoted verbatim.

Appendixes. These include maps, keyword index, and other items.

5.2.2. Off-Battery Hazard Control Plans

An example of an off-battery hazard control plan is the special accident response plan, created jointly by the disaster control agency and the plant operator. Such a plan relates to a plant or works in which, because of the production process, storage, and other features, hazards to nearby inhabitants may occur and disasters cannot be ruled out. The special accident response plan repeats portions of the works alarm and hazard control plan that are vital for response by the agency; these include:

1) Description of the facility
2) Routing of reports and alarms
3) Immediate response to accident/disaster
   - Identification of threat
   - Identification of threatened area
   - Measurement of pollutant levels
   - Warning/notification of populace
4) Subsequent actions

The disaster response plan of a municipality covers all events that may figure in a disaster. It is not restricted to any one plant or works.

5.3. Public Awareness and Responsible Care

Responsible Care. The chemical industry's worldwide responsible care program obliges companies to strive for steady improvements in health, safety, and environmental protection. It mandates that corporations seek a stronger dialog with the public, to enhance public knowledge of product and manufacturing safety.

The centerpiece of an active environmental philosophy, as the Association of the German Chemical Industry made binding on its member companies in 1992, consists of ten Guiding Principles and six Management Practice Codes intended to implement them. CEFIC (the European Chemical Industry Council) has published similar guiding principles for member societies [260].

Member companies are bound by the following guiding principles:

1) To acknowledge the public interest in chemical products and the activities of manufacturers, and to respect this interest
2) To develop and manufacture only those products that can be safely produced, transported, used, and disposed of
3) In the planning of new products and production processes and the improvement of existing products and processes, to assign a high priority to health, safety, and environmental aspects
4) In any chemical-related health and environmental activity, to provide full information to government agencies, employees, customers, and the public, and to recommend suitable protective practices
5) To advise customers on the safe use and transportation of chemical products, as well as their safe disposal
6) To operate production facilities so as to safeguard the environment as well as the health and safety of employees and the public

7) To conduct research to increase knowledge about the possible health, safety, and environmental impacts of products, production processes, and waste products
8) To cooperate with other companies in solving problems occasioned in the past by the handling and disposal of hazardous substances
9) To cooperate with the government and government agencies in devising responsible legislation, procedures, and standards that enhance the safety and protection of the public, workers, and the environment
10) To promote the principles and practices of the responsible care program by sharing experience with all the other companies manufacturing, using, transporting, and disposing of chemical products, offering all kinds of support to them

The six Management Practice Codes deal with:

Information and emergency response
Process and plant safety
Environmental protection
Transportation safety
Occupational health and safety
Product responsibility

CEFIC is promoting and developing the responsible care concept throughout Europe.

Public Awareness. Article 13 of the Seveso Directive for Europe in general, and § 11a of the Industrial Emergencies Regulation in Germany, mandates that the operators of accident-relevant plants provide information on safety practices and proper accident response to persons who may be affected by an accident as well as to the public at large. This information must be made available in suitable form, and without having to be solicited [255].

The objective is to create a bulletin, understandable to the general public, containing the following information:

– Name of plant operator and location of plant
– Name and title of the person giving information
– Brief description of the nature and purpose of the plant
– Identification of substances or preparations that can cause an accident, along with their essential hazardous attributes
– Nature of dangers in an accident, including possible impacts on humans and the environment
– Nature of warning given to affected persons and follow-up
– Correct behavior and actions of affected persons in the event of an accident
– Pertinent safety practices
– Internal and external hazard control plans
– Coordination of plans between plant operator, municipality, and agencies responsible for hazard control

In areas of high industrial concentration, a joint bulletin may be issued by the operators of plants where emergencies may occur.

1. Introduction [1–3]

Work has always involved certain health hazards and risks of accidents. With progressing industrialization the pattern of potential threats to human health at work has been changing. At present, in a highly industrialized society, health protection and accident prevention at work are issues of high ethical and socioeconomic priority.

1.1. History

Work-related health impairments are not a discovery of modern times.

Signs of dust disease of the lungs have been discovered in prehistoric corpses. Scripts from ancient Egypt noted that farmworkers suffered from intense heat and dust on dry soil, whereas working in the muddy grounds along the Nile induced severe rheumatic disorders and chronic arthritis, which still can be seen in mummies. Reports and documentation of occupation-related diseases can be traced throughout ancient history. In ancient Greece Aristoteles and Plato described certain diseases found in specific professions such as "tanners, porters of heavy loads, and couriers." Around 400 B.C. Hippocrates noted: "there are many crafts and arts which cause a number of illnesses and adverse health conditions for those who work in these specific professions."

He also requested that physicians investigate thoroughly the professional history of their patients. Signs of pneumoconiosis and arthrosis of the knee in miners were described by him, as well as the toxicity of lead in lead miners.

Silicosis and diseases caused by lead and mercury or by certain melting procedures in gold mining are reported most frequently in the early European literature.

Georgios Agricola described miners diseases in the early 1500s, and Paracelsus wrote a book on occupational diseases in Germany at the same time.

The Italian physician Bernardino Ramazzini (1633 – 1714) has been called the father of occupational medicine. In *De Morbis Artificum Diatriba* he described different diseases of workmen and their treatment, and stressed the importance of prevention of occupational diseases and accidents to make work "a love rather than a curse." His book includes information on afflictions caused by inhaling noxious gases and dusts, as well as such "modern" issues as illnesses resulting from disorderly motion and improper posture of the body.

With increasing industrialization plant physicians began to take care of workers and their health in the early 1800s. In the second half of the 1800s legislation on health protection and

technical inspection of factories was established, for example, in England and Germany.

Some important events in the history of occupational health are summarized in the following:

B.C.

1500 Description of back pain and deformities in quarrymen (Papyros Ebers).

400 Hippocrates (460 – 377 B.C.) observed an occupational disease (colic) in slaves working in lead mines.

40 Pliny the Elder wrote about lead, mercury, sulfur, and zinc as occupational hazards. He also noted that in dusty conditions workers tied bladders over their mouths to breathe through, and that workers who used asbestos to make textiles became ill.

A.D.

250 Galen identified the danger of acid mists in copper mines.

1473 Ellenbog identified dangers of metal fumes in a report on gold miners. He also discussed carbon monoxide, lead, mercury, and nitric acid, and provided instructions in preventative measures.

1500 Paracelsus (1493 – 1541) wrote a book on occupational diseases, identifying diseases of miners, which he attributed to vapors from the metals. He advised that the vapors be avoided.

1500s Agricola (1494 – 1555) published *De Re Metallica*, a series of books on the hazards of mining. He recommended the use of ventilation in mines and of protective masks to limit exposure to dusts.

1700s *De Morbis Artificum*, a book dealing, among others, with mercury, lead, and the pathology of silicosis, was published by Bernardino Ramazzini, the "father of occupational medicine". He advised physicians to ask patients what their trade was, and to study work environments to learn about occupational diseases.

1775 Percival Pott (1714 – 1788), a London surgeon, identified cancer of the scrotum in chimney sweeps as the first occupational cancer.

1833 The English Child Labour Laws were passed, to limit childrens' working hours, and to provide a mechanism for inspections in certain industries.

1884 In Germany the law on accident insurance for workers was passed.

1925 The first official list of occupational diseases was passed in Germany.

1.2. Differentiation of Tasks

Historically health protection and provision of safety at the workplace has been taken care off mostly by physicians.

They tried to detect work-related health impairments and to discover the causes for these diseases in order to prevent them by changing work hygiene or other conditions at the workplace. In the 1800s close cooperation between physicians and technicians was necessary to improve production processes and working technology to prevent diseases and work-related accidents.

Government inspectors began supervising factories and mines in the second half of the 1800s. At the turn of the century, and specially in the first half of the 1900s, additional groups of specialists developed for specific tasks in the field of health and safety at work.

Nowadays there is a separation of certain tasks covered by different specialists (see Section 1.5). The occupational health physician is responsible for health protection, prevention of occupational illnesses and diseases, accident prevention, and medical surveillance of the workforce. Provision and control of technically safe workplaces, machinery, and working conditions and the technical side of accident prevention is dealt with by safety engineers in most countries. In a number of countries a third group is involved in health and safety at the workplace: the industrial hygienists. Their task is the maintenance of hygienic conditions at the worksite and surveillance of the working environment to identify chemical and physical hazards and give advice on their control and minimization.

In Germany the profession of industrial hygienist has so far not become established. These tasks are taken care off by occupational physicians and safety engineers in close cooperation.

In countries where the occupational health system is not completely separate from general health care, provision of general health care and preventive measures for non-work-related diseases are partially covered by occupational physicians.

1.3. Hazards in the Chemical Industry

Throughout the development of the chemical industry the number of available chemical compounds has grown tremendously. This has led in turn to a broader range of potential health risks caused by chemical compounds. In earlier centuries mostly dusts, fumes, and heavy metals were described as disease-causing agents. Since the mid-1800s organic compounds gathered increasing importance as causative agents for work-related illnesses and diseases.

The specific hazards to human health by chemicals are derived from their general toxicity and from specific properties such as mutagenicity, teratogenicity, carcinogenicity.

The major organ systems affected by chemicals are the eyes (irritation), the skin (chemical burns, allergy), the respiratory system (dust diseases, allergy, irritation), the central and peripheral nervous system (neurotoxicity), the liver, and the kidneys.

The second group of hazardous factors are physical agents such as noise, vibration, heat, dust, radioactive radiation, high pressure, low pressure, and magnetic fields.

The third group of hazardous agents are biological agents, which are gaining in importance with the development of biotechnology and gene technology. Whereas in former times pathogenic bacteria, viruses, and fungi have been known as risk factors in the health- care industry and the pharmaceutical industry during production of vaccines and antibiotics, nowadays microorganisms used in genetic engineering are causing concern as potential health risks.

Developments in the last decades have also attached greater importance to possible health impairments caused by physical conditions such as lifting of heavy loads, monotonous repetitive motions, and improper posture of the body.

Diseases caused by these conditions were already described by Ramazzini. But while in former times humans had to adapt to fit the working conditions – as is demonstrated by the employment of children in certain mining industries – it is nowadays the general philosophy to adjust equipment, machinery, and work-place conditions to the physiological capacity of the human body.

Besides chemical, physical, and biological agents, other factors that have come to be regarded as probable hazards to health in the working population in the last few decades include mental stress and socioeconomic conditions.

The question of occupational disease caused by stress at work is under serious consideration.

1.4. General Outline of Goals

The joint efforts of all parties involved in occupational health and safety at present can be summarized in the following:

1) Prevention of occupational diseases, health impairments, and illnesses caused by influences at work
2) Prevention of work-related accidents
3) Early detection of potential new hazards for human health in the working environment
4) Elimination of identified health hazards and accident sources
5) Adaptation of working conditions, tools, and working environment to the physiological capability of the workers
6) Assistance in providing a socioeconomic work environment to prevent effects on mental health

The means to reach the above-listed goals are:

1) Thorough inspection of the working environment and provision of necessary improvements
2) Provision of a safe technical environment
3) Regular health surveillance and preplacement health examinations
4) Provision of a high standard of hygiene at the worksite
5) Provision of health-supporting socioeconomic conditions

To reach these goals of health and safety provision at the workplace close cooperation of the professional specialists with the employer, employees, and employee representatives is essential.

1.5. Experts and their Training

The tasks of health protection and safety at the workplace are carried out by experts whose professional training and field of expertise varies from country to country.

Occupational Health Physicians. In some countries occupational medicine is a state-licenced speciality of the medical profession. This means that physicians receive additional training in occupational health after several years of medical practice.

In several European countries, training in occupational medicine takes two years, including several months of theoretical study at a university or a special academy. In some countries this additional training leads to certification in occupational medicine, which in Germany includes a state exam.

In the United States a specific training program and residency of two or three years – depending on the university – has been established, leading to the degree of master in public health (MPH). This degree is normally achieved by physicians but can also be acquired by other medical professionals.

In the United States and Great Britain, special training for nurses leads to the degree of occupational health nurse; this is unknown in other countries. The occupational health nurse performs part of the occupational health service in the plant.

Safety Experts. Safety experts normally hold a technical degree, mostly in engineering or chemistry. The special additional education as safety expert or safety engineer differs widely in different countries. Whereas in some countries it is a special academic training with a masters degree or the degree of safety engineer, other countries require only a minor amount of theoretical training parallel to practical experience on the job.

Industrial Hygienists. The profession of industrial hygienist is not yet established in all European countries. It was first developed in the United States and Great Britain, where industrial hygienists hold a specific academic degree in that field. In other countries, such as Germany, industrial hygiene activities are taken care of partially by occupational health physicians or by safety engineers who then are mostly either chemical engineers or chemists by profession.

Worldwide there is wide variability in provision of health and safety services in industry as well as in training and experience of the health and safety specialists.

Many countries are still understaffed and are developing their occupational health and safety systems, with the advise and assistance of more advanced countries. The future goal according to WHO and ILO (International Labour Office) is to provide occupational health and safety services to the entire working population.

2. Legal Background [4–8]

2.1. Laws and Regulations in Germany

The Federal Republic of Germany is a confederation of states. The responsibilities of the government are divided between the Federal Government and the states (Länder) as described below.

Laws, decrees, and guidelines are passed at a national level, the states contributing through the Bundesrat. The states are responsible for the enforcement of laws and for supervising observance of government regulations via their trade supervisory office. In addition to the central government and the states, the legal accident insurance institutions are also involved in the industry-wide occupational safety system. Statutory accident insurance is a branch of social security and is a compulsory insurance. The legal basis of the accident insurance is anchored in the book on social welfare legislation and in the “Reichsversicherungsordnung” (RVO).

The statutory accident insurance institutions are the trade associations. Trade associations are organized according to the specific trade. They have the right to pass accident prevention regulations (UVV).

These regulations serve the trade-specific concretization of governmental laws and decrees.

The relationship between the central government and states on the one hand and the trade associations on the other hand correspond to the principle of subsidiarity. To control the observance of accident prevention regulations, the trade associations have a technical control service (TAD) which assumes control and consultation functions in the factories parallel to the governmental trade supervisory office.

2.1.1. State Legislation and Controls

The enforcement and control of federal laws on occupational safety are the responsibility of the Länder. The State Ministry of Labor (Landesarbeitsministerium) is the highest state authority and is superordinate to the state institute for occupational safety and industrial medicine and the trade supervisory offices. In the application and further development of occupational

safety regulations, close cooperation is required between the participants of the industry-wide occupational safety system and also between the industry-wide and the company occupational safety system.

To guarantee smooth cooperation between the governmental trade supervisory office and the trade associations, the Federal Minister of Labor has passed an appropriate administrative regulation. Apart from the central government, states, and trade associations, private organizations also have important functions in occupational safety.

In Germany, there is a long tradition that private organizations fulfill by means of definitions (e.g., "generally recognized rules of technology") the requirements of federal laws and decrees. These include the standards of the German Institute of Standardization (DIN), guidelines of the Association of German Engineers (VDI), regulations of the Association of German Electrical Engineers (VDE), etc. This is intended to guarantee that occupational safety laws are linked to the further development of technology.

The German Institute of Standardization plays a special role because as far as standardization within the European Community is concerned, it is the direct partner of the European standardization institute CEN/CENELEC.

Private organizations are also active in supervising industrial safety, e.g., the Technical Control Board (TÜV) in the inspection of plant.

The Most Important Laws. The government regulations pertaining to occupational safety can be divided into six areas:

Workplaces, Including Industrial Hygiene. As early as 1891, the first general basic demands on the workplace were laid down in the industrial code. With the workplace decree of 1975, obligatory regulations for the construction and equiping of workplaces were drawn up for all companies.

The individual control areas of the workplace regulations are summarized in the workplace guidelines:

Ventilation
Room temperature
View outside
Artificial lighting
Safety lighting
Floors
Transparent walls
Doors and gates
Glass doors, doors with glass inserts
Protection against falling doors and gates
Automatic doors
Protection against falling objects
Fire extinguishing equipment
Roads
Escalators
Seating
Pause rooms
Rest rooms
Changing rooms
Washrooms
Opportunities for washing outside of designated washrooms
Toilets
Medical room
First-aid equipment
Tempory accommodation for building sites
Washrooms for building sites

Machines, Equipment, and Technical Facilities. Apart from the regulations governing factory premises, a book of rules also exists for the equipping of the premises with machines, instruments, and technical systems.

In particular, the law passed in 1968 governing technical working devices (Equipment Safety Law), the decrees on systems that require monitoring, the Accident Regulations, and the Accident Prevention Regulations should be mentioned here.

The range of the Equipment Safety Law is very wide. It covers not only technical working devices which are used in industrial, manual, and agricultural concerns as well as in the administrative sector, but also machines and equipment used in the private sector, e.g., for the household, leisure activities, recreation, and sports.

The manufacturer and importer are required by this law to put only such equipment into circulation which is safely built. A safety label (GS: tested safety) has been introduced as an orientation aid for the buyer. All machines and instruments carrying this test label have been tested for safety by an officially recognized testing institute.

The most important regulations for facilities that require monitoring are shown in Figure 1.

Figure 1. Important regulations for facilities that require monitoring

The emergence of the regulations for facilities that require monitoring can be understood from the historical development. On examination of complex processing plants today, it is clear that these regulations often cover parts of the plant only.

Therefore, occupational safety in processing plants requires supplementary regulations which take the system behavior into account. Based on the federal emissions protection law, the decree pertaining to industrial accidents (12th BImSchV) covers not only environmental protection requirements, but also occupational safety measures in the case of disruption of normal operation.

This is significant because the operating personnel can be directly affected by the onset, control, and possibly also by the elimination of the results of a disturbance.

Accident prevention regulations occupy the fourth part of the area "machines, equipment, and technical facilities". They contain safety requirements for special machines, equipment, and technical facilities which are used in certain branches of industry.

Hazardous Substances. A modern industrial society is inconceivable without the use of chemicals. Today, it is estimated that more than 100 000 chemicals are used worldwide to manufacture products.

Some of these chemicals are classified as dangerous. Therefore, they may be used and put into circulation only after certain safety precautions are taken.

The Chemicals Law (Chemikaliengesetz) and the decree on dangerous substances (Gefahrstoffverordnung) are the most important regulations.

The Chemicals Law covers not only occupational safety, but also environmental protection and general health protection. Nevertheless, occupational safety is the main focus of the law because in most cases the potential hazard of a substance is first observed at the workplace.

The main emphasis of the Chemicals Law is a testing obligation and a compulsory notification for each new substance introduced to the market. Apart from containing special regulations for introduction into the market, labelling, packing, storage, and passing on of information on occupational safety and environmental protection to users of chemicals, the decree on dangerous substances primarily regulates the handling of chemicals within the company.

This decree demands, in particular, a compulsory inquiry (how and which chemicals are handled within the company), compulsory control (checking the maintenance of stipulated air and biological threshold values, etc.), protective measures to be taken, and prohibition or limitation of use.

To further concretize the decree on dangerous substances, the Federal Ministry of Labor has set up a sociopolitical committee which has the task of elaborating the technical regulations for dangerous substances (TRGS). This committee for dangerous substances (AGS) has passed technical regulations for the following areas:

1) Technical and organizational safety measures (e.g., asbestos: demolition, renovation, and maintenance work)
2) Technical guide concentrations (threshold values for carcinogenic substances)
3) Substitutes and substitute processes (e.g., substitutes for cleansing agents containing chlorinated hydrocarbons).

Regulation of Working Hours. Regulations pertaining to working hours are contained in the working hours code, trading and industrial code, the law regulating the closing time of shops, and the special regulations for the working hours of professional drivers.

The regular daily working hours must not exceed 10 h. Working on Sundays and holidays is basically forbidden. However, there are a series of exceptions:

1) Work that must be done without delay in emergencies or in the public interest
2) Work that is required to prevent the spoiling of raw materials or the failure of production
3) Work that is required to prevent excessive damage when an unforeseeable necessity arises

Protection of Certain Groups of People. The law protecting mothers protects the working mother and the fetus from dangers and health impairments. It protects the mother from excessive demands at the workplace, financial losses, and loss of her job due to pregnancy and delivery.

The law for the protection of children and young persons applies to the employment of per-

sons under 18 years of age. The minimum working age has been fixed at 15 years.

Apart from the laws protecting mothers and young persons, there are also regulations for the disabled and for working at home.

Occupational Safety Organization in the Company. The employer is responsible for the enforcement of occupational safety in the company. He is obliged by law to take all measures required for the protection of his employees in all the occupational safety areas mentioned above, including occupational safety organization in the company. Here, the Workers' Protection Law, the rules for the prevention of accidents, and the labor management act are of special importance.

The Workers' Protection Law requires that the companies engage doctors and qualified personnel for occupational safety. The qualified personnel and the company doctors have to support the employer with regard to occupational safety and accident prevention in all questions of health protection and working safety, including the designing of humane working conditions.

The qualification requirements, profile of duties, and working hours are further concretized in the rules for the prevention of accidents, "Safety Engineers and other Specialists for Occupational Safety" (VBG 122) and "Company Doctors" (VBG 123).

Responsibilities of the Federal Government and the Länder. At the federal level, the Federal Ministry of Labor is in overall charge of occupational safety. In this ministry, drafts of new laws and decrees are elaborated and EC guidelines are translated into German law.

Furthermore, via lower authorities, this ministry supports research and model projects and provides counseling and information.

Supplementary focal points are taken on by other ministries, e.g., the program "Work and Technology" at the Federal Ministry of Research and Technology.

Institutions and Control Functions. The Federal Ministry of Labor is supported by the Federal Institution of Industrial Safety and the Federal Institution of Industrial Medicine.

The duties of the Federal Institution of Industrial Safety include:

1) Cooperation with state officials and with statutory accident insurance institutions.
2) Observation and analysis of occupational safety, health situation, and working conditions in companies and offices.
3) Development of solutions to problems by the application of knowledge of technical safety, industrial medicine, ergonomics, and other industrial sciences. For this purpose, the Federal Institution of Industrial Safety conducts research or awards research grants.
4) Promotion of the application of acquired knowledge through publications, assistance with the defining of rules, development of materials for training and further education, model-like implementation and counseling, exhibitions and professional meetings.

The Federal Institution of Industrial Medicine also belongs to the Federal Ministry of Labor. It emerged from the Central Institute of Industrial Medicine of the former German Democratic Republic and has the following duties:

1) To observe and evaluate the effects of working conditions on health and make contributions to prevention.
2) To conduct and support research on subjects in industrial medicine. The main emphasis is placed on biotechnology and genetic engineering, allergies, stress, hazardous substances, noise, vibration, radiation, dust, and carcinogenic, mutagenic, and teratogenic substances.
3) To collect and disseminate knowledge of industrial medicine as well as to draw up concepts for the care given by company doctors and for health promotion in the company.

The trade supervisory authority that belongs to each state ministry is responsible for technical occupational safety.

This trade supervisory authority is equipped with all the required official powers, especially the right to inspect and check plants at any time. The trade supervisory authority checks that laws, decrees, and other regulations are complied with. Legal occupational safety covers the following:

1) Machines, instruments, plants
2) Hazardous substances, radiation
3) Working hours
4) Social occupational safety (protection of special groups of people)

5) Accident prevention and safety technology

Each trade supervisory office is responsible for all the companies in its area – independent of the branch of industry – and supervises not only the observation of government safety regulations, but also environmental protection. It is also responsible for the granting of exemptions.

The trade medical service also comes under the state ministries and is responsible for medical occupational safety. It is concerned with preventive health protection, such as evaluation of the workplace and medical checkups.

With the help of medical inquiries, this service should elaborate information on possible health hazards caused by the type of work, substances, etc. In addition, it is involved in proceedings for the acknowledgement of occupational diseases.

2.1.2. Trade Associations

Origin, Structure, and Organization. The fundamental activities of trade associations are specified by the Accident Insurance Law of 1884. These are:

1) The private liability of the employer for his employees is replaced by the public law system of statutory accident insurance.
2) Employers in the same or related branches of industry join together to form trade associations. The demands of accident victims are henceforth directed towards the appropriate trade association.
3) The benefits provided by law are granted independently of who caused the accident. The injured person is entitled to this benefit even if he caused the accident himself by thoughtlessness, negligence, or unlawful action. He is denied the benefit only if he intentionally caused the accident.
4) The trade associations are obliged to pursue accident prevention by all suitable means. The employer, who remains fully responsible for occupational safety in his company, receives professional advice and help from his trade association.

The common basis for the social, health, and accident insurance was created by the " Reichsversicherungsordnung" (RVO) of 1911.

At present, the legal accident insurances are divided into one marine, 21 agricultural, and 34 industrial trade associations.

The statutory accident insurance institutions are the federal government, the states, the commune and insurance associations, certain municipalities (cities with their own accident insurance), and the fire department accident fund. The accident insurance institutions are public corporations. They have the right of self-administration, i.e., they carry out the duties assigned to them by law on the responsibility of their own honorary autonomous organs, but under state supervision.

The autonomous organs are the assembly of representatives and the board of directors, elected every six years. They are made up of equal numbers of representatives of the insured persons and of the employers. In the case of agricultural trade associations, representatives of the insured persons and of the employers and of the self-employed make up one-third each.

The assembly of representatives establishes the rules and other autonomous rights of the insurance institutions (e.g., accident prevention regulations). The expenditure of the trade associations is covered by the companies. The employees make no contribution.

This regulation of the fees is based on the fact that the statutory accident insurance is primarily meant to replace the civil liability of the employer for his employees with regard to occupational diseases and to accidents at the workplace and on the road to work.

Further duties of the trade associations include prevention and rehabilitation.

Accident Prevention Regulations. The regulations for the prevention of accidents are the rules of the particular statutory insurer passed according to the RVO and confirmed by the Federal Ministry of Labor.

The employers united in the trade associations and their employees are obliged to observe the accident prevention regulations.

At present, more than 150 regulations for the prevention of accidents exist with different contents. These regulations must be adapted by the individual trade associations to each sphere of responsibility and then passed. Thus, more than 1800 individual accident prevention regulations exist. These regulations control facili-

ties, orders and measures taken for the prevention of accidents, rules of action for employees, requirements for medical examinations, and demands made on the company safety organization. They are supplemented by numerous guidelines, safety rules, leaflets, and brochures issued by the trade associations to facilitate enforcement within the company.

The trade associations have their own umbrella organizations for the areas of industry and agriculture. In the civil service, there is also a head organization: the statutory accident insurance institution.

The main organization of the industrial trade associations looks after common interests and primary duties of the trade associations. These include:

1) Occupational safety, industrial medicine, and first aid
2) Medical and professional rehabilitation
3) Research, testing, and counseling
4) Training and further education of the members of the trade associations
5) Provision of information material
6) Implementation of interstate social insurance agreements

The main organization looks after the common duties of the trade associations in the region through the individual state organizations.

Duties and Control Functions. Each trade association has its own technical control service which supervises the observation of accident prevention regulations. In addition, it counsels companies with regard to industrial safety and health protection. For instance, it can give valuable information on occupational safety prior to the procurement of new machines or the use of new processes. Moreover, the members of the technical control service also work on the further development of the book of technical safety rules in Germany and in the EC. In addition, they advise manufacturers on the safety and ergonomic development of working facilities through the expert committees of the trade associations. The trade associations are also active in the area of occupational medical counseling. Companies that do not have their own doctor can fall back on the doctors of the trade associations' medical service.

In addition, qualified safety personnel, safety representatives, employers and executives, works and staff council members, and company workers are trained in occupational safety and health protection by the trade associations (see Section 2.1.3).

2.1.3. Company Occupational Safety System

The employer is responsible for ensuring that occupational safety regulations are observed. His facilities, measures, and instructions must provide safe and healthy working conditions in the company.

Management must ensure that, as part of their authority to issue directives, all executives and senior employees must regard the practice of occupational safety and health protection as one of their most important executive duties.

In spite of this transfer of duties, the employer alone takes the entire responsibility.

The Specialists. Legal regulations (e.g., workers' protection law) and the rules of the trade associations require companies to provide doctors who are specialists in industrial medicine. The requirements are stipulated in the accident prevention regulation: "Company Doctors" VBG 123 (regulations of the main organization of the trade associations). Company doctors counsel the employer on all matters relating to occupational and health protection:

1) Planning, implementation, and maintenance of production facilities and of social and sanitary facilities
2) Procurement of technical working devices and the introduction of working methods and substances
3) Selection and testing of protective equipment
4) Occupational physiological, occupational psychological and other ergonomic and occupational hygienic questions, which include working rhythm, working hours and pauses, design of workplace, course of work, and working surroundings

Their duties also comprise organization of first aid in the company and questions of changing the workplace and integration of the handicapped into the working process.

Company doctors also perform medical checkups and provide medical care for employees.

The working hours of company doctors are regulated by the trade associations and the public accident insurance institutions in their accident prevention regulations. They depend on the potential hazard of the particular branch and the number of employees.

Company doctors can be employees of the company in question, employees of an industry-wide occupational medical service, or self-employed. The type of medical care is stipulated in agreement with the employer and the works council.

The employer is also required by the workers' protection law to hire qualified personnel for occupational safety. These are engineers, master craftsmen, or technicians with additional training in occupational safety. Apart from counseling duties, similar to those of the company doctors (see above), they are responsible for the technical safety supervision of production facilities and working devices and processes, and for observing occupational safety and accident prevention in practice. Like the doctors, they must inspect the workplaces at regular intervals, report shortcomings to the employer, and recommend measures for their elimination.

Similar to the doctors, the qualified safety personnel has no authority to issue directives. In their work, however, they are free of directives, i.e., not subject to the opinions of company executives when they make demands or have complaints in the interest of occupational safety.

The working hours of the qualified safety personnel are stipulated in the Accident Prevention Regulation: "Safety Engineers and other Qualified Personnel for Occupational Safety" (VBG 122).

Like the company doctors, the qualified safety personnel can be employees of the company in question, employees of an industry-wide technical safety service, or self-employed.

The work of the qualified safety personnel is supplemented by the safety representatives in the company.

In companies with more than 20 employees, safety representatives are appointed by the employer in accordance with the RVO. In their field of activity, they have to pay attention to safety at the workplace. The number of safety representatives depends on the branch, number of employees, and hazard potential of the particular company.

Apart from company doctors, qualified personnel for occupational safety, and safety representatives, other occupational safety experts can also work in the company, e.g., representatives for radiation protection and representatives for biological safety. The experts within the company also include recognized specialists who are authorized to check plants that require monitoring (§ 24 c of the industrial code).

The company representatives for environmental protection (waste, wastewater, and transport of hazardous materials) are also to be taken into account because their duties can partially overlap with occupational safety.

Employees have to support all measures that serve occupational safety. They are obliged to comply with directions of the employer for the purpose of occupational safety. Furthermore, they have to use the personal protective equipment placed at their disposal. Employees must use company equipment only for purposes that are in accordance with the regulations and they need not follow directions that are adverse to safety.

Before taking up employment and with each assignment to a new workplace, the employee is to be informed about the accident and health hazards involved in his work and about the measures and equipment available to avert these risks. These safety instructions can be delivered verbally or in writing. However, the mere handing over of leaflets – without additional explanations – is not sufficient.

If an employee discovers that some equipment is not perfectly safe, he must correct the defect immediately. If this does not belong to his duties or if he does not have the necessary knowledge, he should report the defect to his superior immediately.

If an employee makes use of his right to lodge a complaint about inadequate safety measures with his employer, no disadvantages should accrue to him therefrom. After checking the complaint, the employer must inform the employee about the results and, if necessary, immediately rectify unsafe conditions.

The employee can also lodge a complaint with the works council, either immediately or

after he has unsuccessfully complained to the employer. The works council must check the complaint and, in case it is justified, urge the employer to take remedial action.

Duties of the Works Council. To combat accident and health hazards in the company, all those who can contribute are required to work together. In this connection, the employees have a special role. The German Industrial Relations Act regulates the right of information, participation, and codetermination of employees. The workforce elects and is represented by the works council. The main concern of the Industrial Relations Act is to involve the works council (and the workforce) in all occupational and health protection decisions taken by the employer. With respect to occupational safety, the works council has the mandate to control and organize, the right of codetermination, the obligation to support the authorities, and the right of information and participation.

The works council should ensure that not only the laws, decrees, and accident prevention regulations passed in favor of the employee, but also the negotiated industrial agreements and employment agreements (see Section 2.1.4) are observed and enforced.

The mandate to monitor applies to the occupational safety measures to be taken by the employer and company executives as well as to those to be taken by employees. The works council has the right and the duty to point out shortcomings in occupational safety and accident prevention to the employer or responsible company executives and to press for their elimination with all means at its disposal. The supervisory mandate also includes the obligation to urge the employees to comply with the regulations passed for their protection during the time they spend in the company.

The supervisory mandate is supplemented by the organizational mandate. The works council is required to propose measures that serve the company and the workforce. It can deal with all matters that serve the protection from accidents and health hazards. It can demand from the employer that appropriate measures are taken to eliminate hazards.

According to the Labor Management Act, the works council has the right of codetermination in the settlement of matters of occupational safety and accident prevention. This means that the consent of the works council to the safety measure proposed by the employer is required. It is not sufficient for the works council to simply take note of the intended occupational safety measure. In accordance with the Workers' Protection Law, the appointment of qualified safety personnel and company doctors is also subject to this codetermination.

Based on their obligation to support the industrial safety authorities (trade supervisory authority and trade association), the works council has the duty to support the authorities in their work in the company by providing suggestions, advice, and information.

On the other hand, the authorities are obliged to involve the works council in all company inspections, accident investigations, and in meetings on subjects of occupational safety and to hold discussions, if necessary. Apart from the control services, the works council can also take advice from the qualified safety personnel and from the company doctors. In agreement with the employer, the works council can also consult other experts outside the company. The works council can do justice to its mandate to supervise, organize, codetermine, and support only if it is adequately informed. For this reason, according to the Labor Management Act, the works council is granted an extensive right of information. This right of information is based on the principle that the employer and the works council should have available the same level of information on occupational safety and accident prevention in order to fulfill their duties.

Although the works council has the right to control and participate, the employer carries the sole responsibility for occupational safety. The works council cannot independently enforce safety measures.

The Occupational Safety Committee. All experts for occupational safety in the company are obliged to cooperate. Therefore, the employer is responsible for forming a suitable occupational safety organization within the company.

The central body of the company occupational safety organization is the occupational safety committee. Occupational safety committees are to be formed in all companies in which company doctors and qualified safety personnel

are appointed. The following are members of the committee: the employer or his representative, two members selected by the works council or staff council, company doctors, qualified safety personnel, and safety representatives.

The occupational safety committee is required to discuss matters of concern for occupational safety. It meets at least once every three months. Apart from routine duties, such as dealing with accident statistics or the general supervisory function and coordination, the occupational safety committee should take into account the conditions in the particular company and concentrate its efforts on, e.g.,

1) Counseling and recommendations for safety programs in the company
2) Discussing suggestions for putting into effect safety investments of the company
3) Regular evaluation of the frequency and severity of occupational diseases
4) Analysis of the results of technical safety controls of work processes and the introduction of new working methods or new substances
5) Discussions of proposals for company participation in industry-wide accident prevention measures

In companies with more than three safety representatives and an existing occupational safety committee, it is also required that the safety representatives meet regularly.

In these meetings, the technical safety problems of the individual areas are to be discussed. The safety representatives for the occupational safety committee are to be named.

In smaller companies which have no qualified safety personnel and company doctors, a safety committee is to be formed if more than three safety representatives are appointed. With the participation of the works council, the employer should meet at least once a month with the safety representatives or the safety committee.

2.1.4. Role of the Social Partner and Associations

The function of the unions and the employers' associations are not regulated by law. However, some of their powers are legally described, especially the right to negotiate industrial agreements and to send representatives to certain occupational safety bodies.

Occupational safety and health protection of workers have always been a goal of the unions. Progress has been made in some areas, e.g., a reduction of the number of accidents at the workplace or on the road to work and an increase in the recognition of industrial diseases. However, new problems arise at many workplaces due to job reorganization (e.g., due to stress, performance demands, and new substances).

To attain their occupational safety and health protection goals, the unions work on the further development of the books of rules for occupational safety in both parliamentary and extraparliamentary bodies (occupational safety bodies). Their efforts are concentrated in the sociopolitical bodies of the Federal Ministry of Labor (e.g., committee for hazardous substances), in the advisory councils of the Federal Institution of Industrial Safety and the Federal Institution of Industrial Medicine, and in the aid program "Work and Technology" of the Federal Ministry for Education, Science, Research, and Technology. Moreover, occupational safety councils have been founded in some states with the participation of the unions. However, the most extensive field of action of the unions is the self-government of the trade associations, which comprise equal numbers of representatives of the employer and of the employees. In this connection, unions can be represented by working members or by full-time officials.

Via the autonomous organs (assembly of representatives and the board) and their committees (e.g., accident prevention committee, pension committee), the unions can directly influence the book of rules of the trade associations, help to plan the essential features of the activity of the technical control service (information, counseling, control), and assist in the assessment of occupational diseases and accidents at the workplace or on the road to work.

The representatives of the employer who work in the autonomous bodies of the trade associations can also be the representatives of employers' associations. The resulting common planning platform in occupational safety of trade associations is supplemented by agreements or industrial contracts between the social partners.

These contracts can contain regulations which go beyond the book of rules of the govern-

ment or the trade associations or concretize these rules in a branch- or company-specific manner. For the employees, industrial contracts of this type can be completed only be the trade associations. For the employers, however, both the employers' associations (joint agreements) as well as each individual employer (company or house agreements) may negotiate. The workman's guild and the guild associations are also entitled to complete contracts by virtue of special legal regulations. Where occupational safety was a part of joint industrial agreements in the past decades, it usually applied to the classical areas of working hours, protection of special groups of people, and special allowances.

On the other hand, company agreements contain detailed regulations regarding, e.g., the participation of employees and members of the works council in the enforcement of the Workers' Protection Law and the decree on dangerous substances, or the role of the safety representative.

2.1.5. Future Developments

As a result of the formation of the European Common Market in 1 January 1993, Germany is required to translate European guidelines into German law. Of special significance is the guideline 89/391/EEC: "EEC guideline for the enforcement of measures to improve the safety and health protection of the employee at work". At present, it is being translated into a basic German occupational safety law. The political consultations are not yet completed.

The important points of this EC guideline or basic occupational safety law will be:

1) Extension of the understanding of occupational safety including health protection in the company and, thus, improvement of prevention
2) All workplaces and work processes are to be subjected to risk assessment
3) Employees are to be involved in the shaping of working conditions
4) The control, counseling, and compensation mandate of the trade associations will be extended to include prevention of all health hazards due to work

Due to the "centralization" of the occupational safety legislation in the EC, adaptation of the accident prevention regulations of the trade associations will become necessary. National standards (DIN, VDI, VDE) for machines, equipment, and facilities will be replaced gradually by European standards by CEN/CENELEC.

In Germany, the statutory health insurance companies will also play a new role in future occupational safety and health protection in the company. As a branch of social security, the health insurance companies have been assigned duties in health protection at the workplace in accordance with Section 4, § 20 of the social code. These duties are:

1) To counsel and inform insured persons about health hazards in general and about the prevention of diseases in particular
2) To pursue the causes of health hazards and to work on their elimination
3) To assist in the prevention of health hazards caused by work and to cooperate with the statutory accident insurance institutions (the trade associations)

2.2. Legal Requirements in Other European Countries

Most European countries have specific regulations to protect workers from harm due to work. For some of these countries the regulations are described in more detail below (situation as of December 1994).

United Kingdom. The principal legislative framework is the Health and Safety at Work Act 1974. This sets out general duties of employers and others and is supplemented by specific regulations with more detailed requirements. In the case of chemicals the principal regulations are:

1) Notification of New Substances Regulations 1993 (NONS)
2) Chemicals (Hazard Information and Packaging) Regulations 1993 (CHIP)
3) Control of Substances Hazardous to Health Regulations 1994 (COSHH)

Strictly speaking, NONS and CHIP, both of which are derived from EC directives, deal with the supply of hazardous substances. COSHH, by

contrast, deals with the use of hazardous substances, and with assessing and managing the health risk to employees. If the assessment indicates that there may be risks to health, COSHH requires the employer to:

1) Prevent (by substitution or elimination) or adequately control exposure
2) Make sure that precautions are used and controls maintained
3) Monitor, if necessary, exposure and/or carry out health surveillance
4) Inform, instruct, and train employees as necessary

COSHH contains specific provisions to deal with carcinogens; these implement the EC Carcinogens Directive.

Other regulations deal with more specific risks such as from lead, asbestos, and flammable liquids.

A list of occupational exposure limits (OELs) for use with COSHH is published annually. The list contains two types of OEL. Maximum exposure limits (MEL) are maximum concentrations of airborne substances, averaged over a reference period, to which employees may be exposed by inhalation under any circumstances. The occupational exposure standard (OES) is the concentration of an airborne substance, averaged over a reference period, at which, according to current knowledge, there is no evidence that it is likely to be injurious to employees if they are exposed daily by inhalation to that concentration.

Denmark. The general regulation of chemicals at the workplace is laid down in Order No. 540 of Substances and Materials, which came into force in 1983. (In practice "materials" are considered to be the same as "preparations").

The order establishes some very general provisions for working with chemicals. More specifically it also defines the substances and preparations that are to be considered as hazardous. This Danish definition for workplace purposes is broader than the EC definition, laid down in the 1967 Substances Directive and in the 1988 Preparation Directive.

Included in the definition of "hazardous" are:

1) All substances and preparations classified as dangerous according to the EC directives
2) All substances on the Danish list of OELs
3) All substances on a recommended list (an annex to the list of the OELs) of volatile organic solvents and preparations containing more than 0.5 % of such a substance
4) All substances on a list of agents considered to be carcinogenic and preparations containing more than 0.1 % of such a substance; the list consists of EC carcinogens and IARC carcinogens (Groups 1, 2 A, and 2 B)

The extension compared to the EC definition is primarily for organic solvents. For carcinogens the difference to the EC definition is only small but was substantial until 5 years ago.

For the substances and preparations classified as hazardous specific provisions are given:

1) Substitution/replacement by less dangerous substances if technically feasible
2) Safety data sheets prepared by the supplier, including obligatory information on specific Danish restrictions for use
3) Safety data sheets prepared by the employer (more detailed than those from the supplier)

In more detailed governmental orders, specific rules are laid down for minimization of exposure and for specific types of preparations such as paints.

A specific order prohibits employers ordering persons under 18 years of age to work with preparations containing more than 0.5 % of a volatile solvent.

In general, legislation is similar to the latest EC directives.

Before use of a new substance or new preparation at the workplace the supplier must notify the Product Register at the Danish Working Environment Service. Among other information the notification must contain a full quantitative and qualitative description of the substance/preparation and the amount expected to be sold per annum in Denmark.

Finland. Finnish occupational chemical safety regulations are based on two framework acts: the Labor Protection Act (299/58, amendments) and the Chemicals Act (744/89, amendments). The Act on the Supervision of Labor Protection and Appeal Procedure in matters concerning Labor Protection (131/73, amendments) lays down the rights and powers of the

labor protection authorities. In addition to these, the Occupational Health Care Act (743/78) regulates the occupational health care services which are to be provided to workers.

The Chemicals Act prescribes the requirements concerning chemical substances and preparations as products. The purpose of the Act is to prevent damage to health and environment. Being a framework act, it contains quite general provisions on the duties of manufacturers, importers, and suppliers of chemicals.

With some minor exceptions the regulations concerning chemical substances and preparations as well as safety data sheets are identical with the corresponding EU directives. Under Article 12 of the Preparations Directive, Finnish manufacturers and importers of chemicals hazardous to health are obliged to send fairly detailed information to the Ministry of Labor, which maintains a registry of chemical products. The EU directives regarding restrictions on the marketing and use of certain dangerous substances and preparations have also been implemented in Finnish legislation.

Protection of workers against the risks related to chemical agents is covered by the Labor Protection Act. It also contains general provisions on protection of workers against other hazardous factors at the workplace. More detailed regulations are given in decisions of the Council of State and Ministry of Labor. Detailed regulations have been issued, e.g., on benzene (355/82), lead (1154/93), asbestos (886/87, 1413/91), carcinogenic substances (1182/92, 838/93), and teratogenic substances (1043/91, 1044/91).

The most important regulations concerning exposure to chemicals, however, are contained in the Council of State Decision on the Protection of Workers from the risks related to exposure to chemical agents (920/92, 727/93). These regulations cover widely the obligations of the employer, from assessment of exposure and risk to preventive and protective measures, as well as instructions and information to be given to the employees. The limit values for workplace air contaminants are also specified. Basically, there are two types of limit values. The Council of State issues "binding limit values for workplace air contaminants" which are directly legally binding (e.g., the values for asbestos, benzene, lead, and vinyl chloride). The other type of limit values are the "indicative limit values of workplace air contaminants" (HTP values). The philosophy of the indicative limit values is very close to the concept of the EU indicative limit values. Employers have to take the indicative limit values into account when assessing the quality of workplace environment, exposure of workers, and the meaning of the measurement results.

Spain. Spanish law concerning health and safety at work derives from a number of different sources with varying levels of importance. The Constitution of 1978 requires the public authorities to safeguard workers' safety and health. International obligations such as ILO conventions are included in national law. The Spanish Parliament has adopted a number of specific acts dealing with health and safety, in particular the Workers' Statute of 1980, which states that workers have a general right to be protected by safety rules and the responsibility to perceive the rules adopted by the employer. There are also elaborate administrative regulations establishing the Labor Inspectorate and laying down detailed and technical health and safety rules.

The general principles as laid down in the law are worked out in regulations. The most important of the regulations concerning health and safety at work is the general Ordinance Concerning Safety and Health at Work of 1971, being a tool for the Ministry of Labor to make rules, to initiate research, to give technical guidance, to lay down the functions of the Labor Inspectorate, to establish provincial occupational safety and health councils, to lay general duties on both employers and workers, to set out the functions of occupational safety and health committees and of safety officers, and to make provision for administrative fines.

At the same time there are a number of other regulations which set out specific technical standards, e.g., on protection against lead, asbestos and ionising radiations.

New legislation is designed to bring Spain into line with EC legislation, especially the Framework Directive. Until now provisions have been adopted to comply with the directives on vinyl chloride, lead, asbestos, and banning of certain specified agents and activities. This new law will probably be adopted in 1995.

France. The French laws concerning the risks of chemicals is mainly based on EC directives. For the workplace this means:

1) Risk classification of substances and preparations
2) Notification of new chemicals and preparations
3) Material safety data sheets
4) General prevention rules for workplaces
5) Quality control procedures for workplace air
6) Prevention of cancer risks

There are specific rules and protection measures for women and younger persons. Basis for taking prevention measures is the risk assessment of dangerous substances at the workplace.

Occupational exposure limits (not binding) give indications for protection of workers. At the moment about 520 indicative limit values are available.

The Netherlands. The Working Environment Act (*Arbeidsomstandighedenwet*), adopted in 1980, deals with safety, health, and well-being during work and is meant as a framework law. It comprises basic requirements and responsibilities of employers and employees to be elaborated in decrees and regulations for special topics.

With respect to chemical substances the following regulations are in force:

Relevant decrees are the *Decree on Industry and Workshops* (1938) and the *Decree on Commercial and Noncommercial Services* (1990). For substances a central point is that effective measures must be taken to prevent harm, damage, or nuisance to workers exposed to chemicals during their work. The hierarchy of preventive measures to be taken reads:

1) Prevention of all emissions at source
2) Ventilation
3) Separation of workers and source
4) Use of personal protective equipment

The measures to be taken have to be effective with respect to health protection and prevention of nuisance, but feasibility aspects may also be taken into account. Only in the ultimate case may personal protective equipment be used.

The Minister of Social Affairs has the right to set legal limit values for exposure during work. In March 1994 an initial list of 96 substances with legally binding limit values was published. All these chemicals have passed the Dutch three-step procedure for setting limit values. Additionally, legally binding limit values for 15 carcinogenic chemicals have been covered by a specific decree on carcinogenic substances. In addition to the binding values, administrative occupational exposure limits (MAC values) are in force, adopted from the United States (ACGIH), Germany, Sweden, and the United Kingdom.

The *Decree on Specific Harmful Chemical Compounds* (1991) prohibits the production, storage, and use of certain aromatic amines (2-naphthylamine, 4-aminodiphenylamine, benzidine, and their salts, 4-nitrodiphenylamine). Also, preparations containing more than 0.1 wt % fall under this regulation. It is an implementation of EC Directive 88/642.

The *Decree on Carcinogenic Substances and Processes* (1994) is an implementation of EC Directive 90/394 on the protection of workers from harmful effects due to exposure to carcinogenic chemicals. It covers all chemicals that fall within the criteria for carcinogenicity in EC Directives 67/548 and 88/379.

The decree covers:

1) Registration and evaluation of carcinogenic substances
2) Restrictive working conditions to minimize exposure
3) Setting legal limit values for carcinogenic substances (so far 15 have been published)
4) Medical surveillance, including environmental and biological monitoring and medical investigations
5) Keeping personal log-books of workers involved, which are to be kept for at least 40 years

Moreover, a number of acts have since been published, all of which are appended to the Working Conditions Law. The *Propane Sultone Act* (1976) prohibits the use, production, and storage of this suspect carcinogen.

The *Asbestos Act* (1977) is an implementation of EC Directive 83/477. This Act has been amended several times; the 1993 version prohibits the use and production of all types of asbestos. In situations where significant exposure occurs (e.g., demolition) strict rules and standards apply.

The *Benzene Act* (1977) is an implementation of ILO Treaty 136 of 1971 and restricts the use of this solvent. The *Vinyl Chloride Act* (1987) implements EC Directive 78/610. The *Lead Act* (1988) includes biological limit values for exposure.

2.3. European Legislation

Due to the increasing mobility of the labor force throughout Europe, it is becoming more and more desirable to harmonize regulations and rules concerning working conditions.

As in other matters, the EU Member States try to come to a joint standpoint by mutual discussions. Directives related to working conditions are drafted by the Directorate General V (DG V, Health and Safety) in Luxemburg. These drafts are elaborated in the relevant EC Council working group, leading to a common position. After adoption by the Council of Ministers the new EC legislation must be implemented in national legislation within a certain time period. Since EC workplace legislation concerns minimum requirements (Art. 118 A of the EC Treaty), each Member State has the right to set stricter regulation than specified in EC directives.

Since the 1970s a number of directives on working conditions have been adopted. With respect to chemical substances the following directives, dealing with the protection of workers against health risks of exposure to chemical agents during work, are noteworthy:

Directive 78/610 – vinyl chloride
Directive 80/1107 – a framework directive for chemical, physical and biological agents with general principles of protective measures
Directive 82/605 – exposure to metallic lead and its compounds
Directive 83/477, amended by 91/382 – handling of asbestos
Directive 88/642 – binding and indicative limit values
Directive 88/364 – relating to the banning of certain agents
Directive 90/394 – the carcinogens directive
Directive 91/322 – establishing indicative limit values for 27 substances

Since 91/322 a multistep procedure has been followed to develop additional indicative limit values. As a first step the Scientific Expert Group (SEG) of DG V establishes a health-based recommended value; in the next step the socioeconomic and technical feasibility of the SEG value is investigated by the Commission, the Member States, and the tripartite Advisory Committee on Safety, Hygiene, and Health Protection at Work. In the third and last step the committee of Member State representatives votes on the Commission proposal for a definite indicative limit value.

As of December 1994 a number of SEG recommendations has been published. The next steps in the procedure, however, have stagnated seriously.

A Commission proposal [COM (93) 155 final – SYN 459] for a council directive on the protection of the health and safety of workers from the risks related to chemical agents at work is under discussion in the Council working group.

100 A-Directives. In addition to the specific 118 A-workplace directives, a number of 100 A Common Market Directives also have important implications for workers.

Most prominent is Council Directive 67/548/EEC of 27 June 1967 relating to the classification, packaging and labelling of dangerous substances, as amended by Council Directive 92/32/EEC of 30 April 1992. The sixth amendment (Directive 79/831/EEC) concerns notification of new substances. In the seventh amendment (1993) the risk assessment paragraph has been worked out extensively.

Further Council Directive of 26 June 1978 relating to the classification, packaging, and labelling of dangerous preparations (pesticides), and Council Directive 88/379/EEC of 7 June 1988 relating to the classification, packaging, and labelling of dangerous preparations, as amended by Council Directive 90/492/EEC, defining and laying down a system of specific information on dangerous substances and preparations, in the form of safety data sheets, are principally intended to enable industrial users to take the measures necessary to ensure the protection of the safety and health of workers.

2.4. Regulations in the United States

Industrial safety and health in the early stages in America changed from work-related accident

and illness being the worker's responsibility to a team approach of worker and management. Some industrialists realized early that unhealthy or unsafe work conditions cost money, with lowered work quality, interrupted work schedules, and compensation payments to injured or sick workers. Others refused to recognize the inherent hazards of their business, and this required a series of regulatory requirements for adequate controls to be introduced.

The Occupational Safety and Health Act (OSHA) of 1970 authorized the Department of Labor to set and enforce mandatory occupational and health standards for businesses. The act provided for research and assistance with the discovery of latent data to establish any connection between diseases and the work environment. While other laws gave the authority to regulate food additives, drugs, and pesticides for public exposure, no employer was previously required to assure worker health in production operations. OSHA is unique because it does not have authority to pre-approve products entering the market, unlike FDA and EPA. Furthermore, OSHA cannot require mandatory testing of products.

The Act created the National Institute of Occupational Safety and Health (NIOSH) under the Department of Health and Human Services, with responsibility for research and recommendations for reports on employee exposure and the authorization of medical examinations and tests where desirable to protect employees.

OSHA health standards typically set maximum limits on employee exposure and prescribe procedures or equipment to achieve this level. The Environmental Protection Agency (EPA) under the Toxic Substances Control Act (TSCA) requires disclosure of safety information and testing to develop data for health and environmental effects for chemicals intended for manufacture, import, or distribution. Testing is initiated by the finding that a chemical presents a potential risk or that humans will be exposed to substantial quantities. With the different regulatory agencies involved (federal and state), there is potential for inconsistency in government standards.

The Interagency Testing Committee, now the Regulatory Council, had the goal of securing agreement on requiring chemical-specific testing and common policies. Agencies have also achieved collaboration in the National Toxicology Program (NTP) to coordinate numerous federal efforts to improve methods and performance of animal studies on selected chemicals, funded by public taxation.

Another joint effort is the Agency for Toxic Substances and Disease Registry (ATSDR) under the Public Health Service, where the EPA publishes toxicological profiles of chemicals determined by the collaborators to be the most significant potential threat to human health.

In summary, the Federal Government's Occupational and Health Administration, in cooperation with state agencies, sets and enforces standards for production and process workers. Other agencies (EPA, FDA, and Consumer Product Safety Commission) have various laws on packaging, transportation labels, and pre-marketing requirements to protect consumer health and the environment. To combine efforts, OSHA has published a standard on Hazard Communications (1986), which includes requirements for material safety data sheets and labels for hazardous products.

3. Industrial Hygiene [9–28]

3.1. Introduction and History

Introduction. Industrial Hygiene (IH) is a term given in the United States primarily to the discipline broadly concerning the recognition, evaluation, and control of the chemical, physical, and biological stressors that may cause discomfort to or impair the health or well-being of employees in the workplace. Such stressors may result from exposure to:

1) Chemical gases, vapors, fumes, particulate matters, etc.
2) Physical agents such as noise, vibration, heat, and cold
3) Ionizing and non-ionizing radiation
4) Biological materials or microorganisms
5) Ergonomic stress

In a number of European countries this discipline is defined more appropriately as Occupational Hygiene (OH), and this term, originating from the United Kingdom, is generally used in these Sections. In other countries (e.g., Germany) the term industrial hygienist or occupa-

tional hygienist is less well-known, and the general functions, defined above, are generally performed by specialized safety or medical personnel.

The main objective of occupational hygiene is the prevention of undesirable effects to health by assessing and adequately controlling harmful exposures to chemical, physical, and biological agents in the workplace. While safety is more broadly dedicated to the prevention of personal injuries and loss of assets and equipment resulting from sudden events and failures, OH focuses on potential hazardous exposures arising from short- and long-term working conditions.

Occupational medicine, also concerned with health protection, monitors for any early signs of illness by means of a health surveillance program on individual workers. Proper interaction and communication between occupational hygiene and occupational medicine guarantees a comprehensive and truly preventive occupational health program.

History. Occupational diseases were identified more than two millennia ago by the Greek physician, Hippocrates, who described lead toxicity in mining (400 b.c.). It is only since the early 1900s, however, that the dimensions of the problem of health and safety of workers have raised general interest and stimulated legislative actions in some industrialized countries.

During the long intermediate period, occupational health remained dormant, with the exception of a few, far-sighted persons who studied and recorded the problem in now famous treatises. Among them are Agricola (1500s), who in his *De Re Metallica* described a lung disease caused by the inhalation of silica (silicosis); Paracelsus (1567), the father of modern toxicology; and Ramazzini (1700s), who first outlined preventive measures for various occupational hazards in *De Morbis Artificum*.

Despite the enactment of some well-meaning legislation and the establishment of public health services in the United States and many European countries, working conditions improved little, and statistics continued to show high incidences of both injury and illness at work until the end of World War II. It was during this period that the first occupational hygiene services and associations were formed in the United States. With the exception of the United Kingdom, occupational hygiene in Europe came later, and a leading role in this field was played by occupational physicians from public services, universities, and industry.

The explosive technical progress in all scientific fields since the 1960s and the enormous development of different industrial activities and services (extractive, chemical, pharmaceutical, agrochemical, automotive, transport, nuclear, electronic, etc.) have required a new and more specialized effort in the increasingly complex field of health and safety at work.

A strong safety culture has been established by industry during this period. This resulted in programs which broadly incorporated health and environmental protection, and aimed at protecting key assets (people, property, and technology). Workplace conditions have progressively improved, as demonstrated by positive trends in safety records for occupational injuries and illnesses. New factors have more recently emerged which have modified public awareness of health and environmental matters, changed priorities and expectations on quality of life, and, in general, reduced trust in industry and its ethics.

The scientific knowledge of the effects of chemical, physical, and biological agents on human health gained by toxicologists and health professionals has increased dramatically, together with the analytical ability to measure smaller and smaller amounts of substances in any media (air, water, soil, food, biological fluids, etc.). Scientific and social standards of acceptability for both workplace and environmental pollutants have continuously been lowered. In addition public perception of the risk arising from chemicals changed after recent industrial disasters which damaged and threatened entire populations (Seveso, Bhopal, etc.). Regulations have become increasingly stringent and sometimes bureaucratic and complex. Industry has recognized these concerns and is working to rebuild confidence and trust with more transparent and coherent environmental, health, and safety (EH & S) programs. In particular, the chemical industry has relaunched its commitments by voluntary worldwide implementation of the Responsible Care program, with excellent and measurable performance in integrated EH & S as the main objective.

In this new climate the role and function of cost-effective occupational hygiene services can

significantly contribute to the goal of protecting and promoting the health and well-being of workers and the community.

3.2. Requirements for an Effective Program

There are no consolidated and internationally accepted requirements for establishing an effective occupational hygiene (OH) program, and different approaches have been adopted in various countries, appropriate to national legislation, cultural background, and needs. Attempts to harmonize OH practices are being made by international associations and standardization bodies [e.g., ILO (International Labour Office), WHO (World Health Organization), EC, etc.] but the quality of service varies considerably, particularly in Europe.

Public OH services exist in many countries. They are usually part of the governmental health and safety institutions, which may have an advisory role and/or assure compliance with legislation. Other services are part of academia and may act as consultants for the government and for companies.

Most large companies have in the last decade established an internal OH service, usually as part of the environmental, health, and safety organization. Private consultancies have developed in some countries, and also represent a resource for medium-sized and small companies that cannot afford an in-house service.

Experience gained from well-run and successful services, particularly in multinational chemical and petrochemical companies, indicates that a number of key basic elements and systems should be considered and implemented. The philosophy and detailed practical guidelines for each element are described in the following sections of this chapter.

3.3. Objectives and Standards

Independent of the nature and size of the OH service, the first and most important factors to be defined with full agreement and committed support of top management, is the definition of mission of the service, together with long- and short-term objectives.

The mission statement together with well-defined objectives will clearly indicate the core values the service is aiming at and provide directions, means, and ethical provisions which will be adopted to achieve the mission.

In addition, the OH service should define the level of standards strived for in the various program elements. In some cases the reference standard can simply be national legislation and practices; in other cases, for large multinational companies, stringent internal requirements are set to guarantee high-quality and consistent working conditions, independent of the local country's economic and social structure, legislation, authorities, and verification of compliance.

Corporate codes of conduct and guidelines should also be issued to harmonize practices and to help implement the programs. Periodic review and adjustment of the objective should also be instituted, together with an auditing system to measure the performance of the service against the targets.

3.4. Organization and Staff Management

The second essential element for an OH service is an adequate organization, sufficiently staffed and well managed, in which allocation of responsibilities is clearly defined. It is clearly specified in all legislations that the health and safety of employees is the responsibility of the employer, and not of the safety, medical, or OH services. The role of the service is to provide management and employees with technical and scientific opinions, expert advice, and authoritative input for implementation and interpretation in the OH field. This is a clear advisory function in which the occupational hygienist should maintain his professional independence and ethics.

Typically, an occupational hygienist has a university degree in science (e.g., chemistry, biology) or engineering, or a specific degree in occupational hygiene or environmental health, plus postgraduate specialization in industrial hygiene/occupational hygiene and accumulated practical experience in this field. This broad, basic knowledge in a variety of disciplines, which should also include elements of toxicology, occupational medicine, safety, environmental protection, ergonomics, analytical chemistry, and

statistics, allows the occupational hygienist to perform well in a complex workplace environment.

Codes of ethics for this profession have been established by some national and international associations [e.g., AIHA (American Occupational Hygiene Association), IOH (Institute of Occupational Hygiene), and IOHA (International Occupational Health Association)]. In addition, there are well-known, highly reputed, professional certification schemes in the United States and the United Kingdom [ABIH (American Board of Industrial Hygiene) and BERBOH (British Examining and Registration Board in Occupational Hygiene)], with the aim of elevating the level of professionalism and guaranteeing high standards. These independent institutions provide certification by examination at various levels of competence and specialization. The ABIH also requires periodic re-training and qualification in order to keep the certification.

It is important that the professional OH service not become disconnected from workplace practices or be regarded as a consultative body. Continuous links with management can be established by implementing a so- called OH unit contact concept. Well-trained persons can be nominated as OH contact in the production unit or plant where they work. In this function they carry out specific routine tasks on a daily basis under the technical assistance of the professional OH staff. These tasks can include sampling and analytical activities, workplace observation, and self inspection. Good cooperation and balanced approach between OH contacts and the professional OH organization is instrumental in the effectiveness of the program. A similar approach with a part-time person, eventually trained and supported by external services, can be adopted by small to medium-sized companies, for which the hiring of a professional OH is economically infeasible.

Continuous communication and good teamwork is needed between the two main health professionals – the industrial hygienist and the occupational physician. This is particularly important in areas where knowledge of each other's findings and data is essential for a truly preventive occupational health program (work history; job class; exposure data; biological monitoring; first aid, acute and chronic cases; health surveillance trends, etc.). Good communication and cooperation should also be sought with other related expert functions, such as safety and environmental protection due to the overlapping and often conflicting fields of interest (e.g., communication and training of employees, personal protective equipment, job safety analysis and working procedures, auditing, ergonomics, accident investigation, air pollution, and emergency responses).

3.5. Anticipation of Health Hazards

The early anticipation of health problems is probably the most cost-effective practice of occupational hygiene. It consists of identifying and correcting sources of exposure or potential health-affecting situations early in the design stage of new facilities and when modifying existing ones. It is cheaper to make changes at the design stage than to retrofit processes when in operation. Although the concept is very straightforward, it is not easy for the engineering/construction group to foresee and minimize all possible factors adversely affecting the project (e.g., process yields, quality, performance, reliability, environment, health, and safety). If the occupational hygienist is involved, for example, at the research and development stage, he can review the properties and intended use of new products and processes. He can help determine additional toxicological testing if necessary, in order to make a preliminary hazard assessment.

Similar assistance should be provided when a material new to a facility is introduced or handled. In this case one should also search for existing occupational exposure limits (OELs) and the availability of adequate sampling and analytical methods in case quantitative evaluation is required. Advice on ergonomically designed equipment, workplaces and procedures, requirements for appropriate hygiene and facility decontamination, and selection and testing of machinery based on specifications driven by health hazard considerations, are other examples of anticipation. Major maintenance work or shut-down operations, which currently represent the conditions with the highest risk level, are also cases where a program should be specially designed to prevent major exposure problems during execution. Consultation of OH be-

fore acquiring an existing facility should also be considered by large companies.

3.6. Occupational Exposure Assessment

3.6.1. Introduction

Research and development (R & D) activities, manufacturing operations and related services (e.g., maintenance, utilities), transport and distribution, end-use and disposal of products are all stages at which, in spite of technological progress, the personnel involved may be exposed to workplace pollutants. This section describes the most traditional and fundamental function of an occupational hygienist: the assessment of exposure to chemical, physical, and biological agents. The more accurate the assessment, the more valid the determination of related health risks that the occupational hygienist and other health professionals can then make.

Appropriate risk assessment allows the risk manager to take the most effective measures to control hazardous exposure and ultimately assure a safe and healthy work environment throughout the working life of all employees. Exposure assessment can be carried out by various methods, which often reflect the different legislative emphasis and OH traditions. The strategy for an exposure assessment described here is a general and simplified one which reflects current accepted good practice and is founded on a preventive philosophy. This strategy is outlined in Figure 2 as a cyclic sequence of steps which are broken down into subsets and described in detail in the following sections. The entire process starts again when a re-assessment is needed due to significant process and procedure modifications, or simply because of ageing of the unit. It is good practice to consider re-assessment every four to five years if exposure conditions have not changed prior to that time.

3.6.2. Characterization and Identification

The first step in occupational exposure assessment is collecting and evaluating the relevant information, documents, and reports that allow full recognition and characterization of the factors and conditions leading to hazardous exposures. This is the preparatory stage upon which the entire assessment is built. The various factors that influence the degree and frequency of exposures depend on the type of work and working environment, how the personnel operate, and the nature of the agents. All these intimately interconnected aspects, once properly described and examined, provide the basic information for the assessment process.

To properly conduct this step, the occupational hygienist should become very familiar with the unit/plant under investigation, and spend sufficient time collecting information, studying, holding discussions with supervisors and workers, and observing what happens in the process. Naturally, previous OH data and experience, if available, are a fundamental source of information. The information, answers, and factors that generally have to be gathered during this preparatory phase are listed in the following:

Work environment and process:	Type of process and technology, chemistry and operating conditions
	Type of production and variation (continuous, batch, etc.)
	Layout and building characteristics
	Equipment and machinery
	Degree and type of environmental controls
	General and local ventilation systems
	Main emission sources and propagation
	Seasonal variation
	Maintenance requirements
	Hygiene facilities
Workforce and human factors:	Number of people, age, sex
	Shift system
	Awareness and training
	Personal protective equipment
	Workclothes
	Food and drink consumption
	Routine operations and tasks
	Infrequent and critical tasks
	Typical length and frequency
	"Dirty jobs"
	Special groups at risk
	Contractors
Agents and their characteristics :	List of chemical substances (raw materials, intermediates, byproducts, products, etc.)
	Physical and warning properties
	Noise, vibration, heat stress, and other physical agents
	Toxicological profile and main health adverse effects
	Acute, chronic, carcinogen, mutagen, reproductive
	Immediate or delayed
	Reversible and irreversible
	Asphyxiant, irritant, allergenic, etc.
	Biological agents
	Route of exposure (inhalation, ingestion, skin contact)
	Applicable occupational exposure limits (OELs)

Figure 2. Outlines for an occupational exposure assessment

A list of typical areas, operations, and conditions where experience has shown that higher risk of exposure can occur is as follows:

Warehouse	Sampling raw materials Fork lift trucks
Unloading/loading stations	Ship, barge, rail car, tank truck unloading/loading operations Handling bags/sacks/drums
Laboratories	Handling incoming samples Storage and handling of reagents/solvents Lab waste disposal/glassware washing
Process area	Tank vents, pumps, centrifuges, filters, dryers, extruders, grinders, mill furnaces, process sampling, adding raw materials, filling line, packaging and bagging operation, waste handling
Maintenance and mechanical shop	Decontamination and line breakup Welding, soldering, cutting, grinding, machinery degreasing, polishing, sand blasting, vessel entry, and confined space operation

The list is not exhaustive and refers to chemical production facilities, but can be extrapolated to other operations.

3.6.3. Preliminary Evaluation and Prioritization (Qualitative Assessment)

By using a systematic approach and documenting the preliminary evaluation as described in recent publications or recommended by some codes of practice based or legislation (Germany, United Kingdom, EC, etc.), the preliminary evaluation becomes a valid qualitative assessment of health risks. In addition, it can constitute the basis for a system for prioritizing potential OH concerns so that resources can effectively be directed to those conditions that pose the greatest risk. This prioritization scheme is determined by the qualitative assessment and monitoring results, but can also be used to establish priorities in other important areas, such as exposure control, communication, and training of employees.

Preliminary assessment consists of estimating the nature and degree of exposure, combining considerations of type and extent of health effects, and finally deriving a sound judgment of the overall related risk. The degree of exposure is estimated by reviewing the information collected during basic characterization with one or more of the following tools: previous monitor-

ing data, experience from similar conditions, exposure modeling techniques, semi-quantitative field monitoring, and spot measurements. Qualitative ratings or indices can be established for typical exposure categories for tasks performed by homogeneous exposure groups: 0 = none or negligible, 1 = low and infrequent, 2 = moderate and infrequent, 3 = high and frequent.

Similarly, toxicological properties, related health effects, OELs, or other parameters can be used to qualitatively classify the hazards of agents: 0 = minimal/low effects, 1 = moderate/reversible, 2 = moderate/high, 3 = very high/ irreversible. Lack of OELs does not prevent assessment but makes it more complicated. A useful approach is to assign to the agent a more stringent priority category where doubts exist.

By combining the degree of exposure ranking and the hazard classification of agents, it is possible to assign an overall qualitative risk index and prioritization to the various homogeneous exposure groups or working areas. In most modern workplaces, which are characterized by an enclosed and fully automated process, the assessment normally indicates negligible risk and low OH priority; few are normally judged unhealthy and require control (Fig. 2); some others cannot be properly evaluated with a qualitative method and require further, quantitative assessment. The above rating refers to routine, normal operating, or planned conditions and cannot be used for emergency and unplanned operations.

3.6.4. Occupational Exposure Limits

Occupational exposure limits (OELs) are the most traditional and widely used criteria to assess the acceptability of workplace conditions. The various types of OELs for chemical and physical agents are established by means of different approaches, purposes, definitions, and updating systems by various national and international regulatory bodies. Most are guidelines for evaluating health hazards and assisting in other preventive activities (adequacy of control, design standard, selection of PPE, etc.). Others have legal status and serve for demonstration of compliance. OELs are based on current knowledge of toxicological and health effects of the substance on the working population, and on the best judgment of health scientists and occupational health professionals.

In general, an OEL for a chemical substance refers to the airborne concentration to which most workers can be repeatedly exposed by inhalation for a full working day and working lifetime without adverse short- or long-term health effects. However, OELs do not guarantee complete protection of all workers and cannot be used as an absolute dividing line between safe and harmful concentrations, but only as a guideline.

OELs have a long tradition worldwide, and the first recommendations were published in Germany by Lehmann in 1889. A systematic development of OELs started in the United States in the mid-1940s with the ACGIH-TLV system which has remained the most widely used and highly reputed system to today. Germany started an independent MAK system in 1965, and after this other nations started their own national schemes (Sweden, United Kingdom, France, The Netherlands, Denmark). In 1977 the International Labour Office (ILO) in Geneva published its "air quality limits" for the workplace, followed in 1980 by the WHO with "safe limits" for occupational exposure. The ILO and WHO OELs are health-based limits established solely by considerations of the health of the working population. Most other OELs, especially those with regulatory compliance status, incorporate other technical considerations (technical feasibility, analytical methods) as well as socioeconomic factors.

In light of the differences that exist between OELs from country to country in Europe, which is also influencing the principle of free movement of labor, the EC Commission began in the 1980s to tackle the problem by offering a scheme to harmonize OELs in the Member States and to coordinate the activities of the national bodies. More than 1500 of the most important chemical substances now have an official OEL established by combining the activities of the various agencies around the world, and many hundreds more are set internally by international enterprises. Although these limits are relevant for many key occupational health concerns, the very large number of chemicals on the market (100 000) represents a complex challenge for both authorities and companies.

When no OEL has been established for an existing chemical (particularly common in the case of process intermediates) or for a novel substance, assessment becomes more complicated, and assistance from other health professionals (occupational physicians and toxicologists) is necessary. A program to obtain a minimum set of toxicological data with the aim of establishing a preliminary OEL or internal guideline is required.

Different categories of OELs are established to take into account the toxicological properties and related health effects of the substances. The most common category is the TWA concentration for a defined period of work (normally 8 h). A defined number of excursions above the TWA are allowed per shift, taking into account the short-term effects of the substance (Short-Term Exposure Limits, STELs). For certain substances, where exposure can result in acute health effects, there is a ceiling limit that describes the concentration beyond which workers should not be exposed under any circumstances.

For a limited number of chemical substances, a biological exposure limit has been established. This provides criteria for carring out and evaluating a biological monitoring program which assesses the overall internal exposure to the chemical by analysis of biological samples. It should complement the traditional OH airmonitoring program.

3.6.5. Quantitative Assessment – Occupational Hygiene Monitoring

The preliminary assessment step indicates, in order of priority, which exposure conditions, related agents, groups of workers, and homogeneous job groups need to be assessed by an appropriate monitoring program.

The objective of this section (see also Fig. 2) is to analyze the elements and provide guidance on how to plan, conduct, document, and maintain records of an investigation evaluating exposure of workers to chemicals.

The technique for evaluating exposure in the workplace has changed in many ways over the years. Work situations in which workers are clearly and grossly exposed have declined; in most cases, the levels of exposure are quite low. A quantitative assessment of very low levels of complex chemical mixtures is a challenge requiring professionalism, experience, and a carefully thought out working model. Before the start of any monitoring, the preparation of written plans for appropriate monitoring (protocol) is the first step to assure the required level of quality, reliability, and effectiveness of the entire program.

3.6.6. Monitoring Planning and Strategy Definition

There are many reasons for conducting an OH monitoring program besides evaluating personnel exposure: to demonstrate regulatory compliance, verification of applied control, selection of PPE, continuous air monitoring for leak detection and air emissions, etc. Each requires a different strategy. The first elements of a monitoring protocol should state clearly the purpose of the program and define the most appropriate strategy to accomplish these objectives. A detailed and in-depth review of information and data collected during the preliminary assessment, specifically related to the agents and workplace prioritized for the monitoring, is then required. Defining a monitoring strategy simply means answering the basic questions what, when, how, how long, and how frequently sampling should be carried out.

Typical workplaces are complex, and concentrations of environmental agents vary temporally and spatially within and between workdays. Workers move through these variations in concentration in variable patterns, and they also influence the concentration and the degree of workplace contamination by the tasks that they perform. The exposure routes by which workers can absorb a substance must be carefully studied in relation to its physical, chemical and toxicological properties. Inhalation is usually the primary mode of exposure, and this depends on the vapor pressure of the substance, temperature and pressure of the process, etc. Absorption via skin contact can also be significant, especially if the substance readily penetrates the skin in toxic amounts. Exposure via ingestion is generally negligible, but it is necessary to watch for

potential intake via food, beverage consumption, and smoking.

The toxicological properties of the substance and its potential health effects should be reviewed in detail: how it exerts its acute properties; the type of chronic toxicity; the target organs; the carcinogenic, reproductive, and neurotoxic potential; the reversibility or irreversibility of the effects; and the biological half-life, etc. A careful review of the documentation of the OEL of the substance is necessary in order to understand the rationale and the safety factors adopted.

There are two major categories of sampling strategy: traditional and statistical. In practice there is a third category that results from specific regulatory requirements, where approach, methods, procedure, etc. are indicated by the legislation. The traditional diagnostic approach is based on past experience and professional judgment of the industrial hygienist. It is normally an effective combination of the most common types of sampling: personal, task, and stationary sampling. TWA personal sampling is performed by taking samples with miniaturized devices in the breathing zone of a worker for the entire shift (ca. 8 h). This is the preferred and most effective technique to evaluate exposure.

Task-related sampling is carried out, for example, at the workers' breathing zone during potentially critical operations and tasks. Stationary sampling, carried out in strategically fixed locations of the process, is generally useful in identifying the source of exposure and can be used to estimate worker exposure if other sampling is impractical. Continuous air monitors are generally sophisticated stationary sampling systems equipped with alarms, which are installed to measure one or more chemical agents in various selected parts of the process area. They can be used as leak detectors and for monitoring background concentrations.

There are various statistical approaches reported in the literature and specifically recommended for regulatory compliance. The selection and application of the most appropriate and powerful statistical model, backed up by sound professional judgment, can result in enhancement of the overall quality and credibility of the program.

Frequency of sampling is dictated by statistical considerations, and largely depends on the variability of the conditions being sampled. The more variable the conditions are, the more samples are required. However, 5 – 8 sampling repetitions is a good rule of thumb, valid for most conditions. Different shifts should be sampled for the same homogeneous exposure group. Work load, seasonal, and evironmental conditions should be considered. The conditions during sampling should be representative of the conditions that one intends to evaluate.

Estimation of potential for skin contact can be made by measuring surface or item contamination by wipe-tests. Choosing an adequate analytical method to match the selected sampling strategy is the next step, and often requires help from analytical chemists.

The final important elements of a monitoring protocol include a careful timetable and cost estimate for the entire program. Extensive monitoring can become extremely expensive and may not be necessary and/or add very little valuable information to the assessment. A proper balance between needs and scope of monitoring and cost should be the goal.

3.6.7. Sampling and Analysis; Data Quality Assurance

Sampling equipment and analytical techniques for air monitoring have undergone marked changes over the past decades, with improved detection sensitivity, miniaturization, and automation.

For the most important chemical agents, specific and reference methods are published by the National Institute of Occupational Safety and Health (NIOSH), and DFG (Deutsche Forschungsgemeinschaft). These methods generally describe sampling, analytical procedure, and instrumentation and specify the important parameters that have been determined in laboratory and field tests to satisfy good practice for trace monitoring. Generally the range of applicability, stability, recovery, effect of humidity, interferences, limits of detection, accuracy, and precision are indicated. When a reference-validated method is available and its field of application satisfies the needs of the planned monitoring strategy, the normal quality assurance tests, such as instrument calibration, blanks, and known standard samples should be run to verify

that the sampling and analytical conditions chosen correspond to those of the validated method. If no method is available, a plan for its development should be designed in cooperation with analytical chemists. Air monitoring techniques, which are highly developed because OELs are generally based on inhalation exposure, can be conducted by:

1) Collecting contaminated air in glass bulbs, plastic bags, etc. for later analysis
2) Instruments and techniques that directly measure the pollutants in air
3) Removal of the chemical agent from the air for later analysis

Direct-measurement techniques range from relatively simple colorimetric detectors to highly sophisticated portable infrared detectors or gas chromatographs (GC). They are extremely useful as preventive tools when equipped with alarm systems, or in diagnostic evaluation.

The most widely used techniques fall into the third category, where a volume of air is drawn by a pump (active system) or diffusion (passive) into an appropriate collecting medium, either solid (e.g., charcoal tubes) or liquid (e.g., solvent). This is generally used for vapors and gases, which are then extracted and analyzed. Similarly, filters or membranes are used to remove airborne particulate matter (dust and aerosols) from pumped contaminated air. When a specific fraction of the particles (e.g., inhalable fraction) is to be measured, an appropriate size-selecting device is placed before the membrane.

Common analytical techniques include GC, Atomic Absorption (AA), HPLC, and GC – MS. Classification and counting under the phase-contrast microscope is carried out for airborne fibers (e.g., asbestos).

3.6.8. Sampling and Analysis Execution

Good communication and arrangements should exist with the unit and analytical lab supervision prior to the sampling and analytical execution in order to take into account production schedule changes, etc. This is particularly important when monitoring specific and infrequent tasks. Sampling preparation often requires calibration of sampling devices and instrumentation, and labelling of tubes, badges, vials, and bags.

During sampling execution, it is advisable to use predefined sampling record forms, in which the key information and observations noted during sampling are written down (humidity, setup conditions, use or not of personal protective equipment, etc.). Handling, temporary storage, and transportation of collected sample to the laboratory should be done according to planned procedure to minimize errors and prevent invalidation of results.

3.6.9. Data Interpretation and Reporting; Record Keeping

Once the analytical results have been converted into appropriate units (e.g., ppm), they must be grouped into meaningful categories (TWA personal data of each homogeneous exposure group, the STEL results of similar operations, etc.) and then studied by adding the information noted during sampling. Appropriate statistical tools are then used to describe the central tendency of samples (e.g., arithmetic mean) and their distribution (range, geometric standard deviation, etc.). Ultimately, the best estimate of exposure is compared with the OEL to determine the acceptability of the assessed exposure conditions.

Another possible interpretation is that it is not possible to make a decision with the data available, and further monitoring is necessary. If the sampling strategy includes a specific statistical analysis, additional and more precise conclusions can be drawn (e.g., chance of exposure above the OEL).

The main elements of a quantitative assessment should be documented in an appropriate survey report. This should include purpose, information on the process/unit and homogeneous exposure groups, OELs and criteria of evaluation, sampling and analysis, data quality assurance, tables of results, conclusions, and recommendations.

Because much of the information is already available in the monitoring protocol, proper use should be made of existing documentation and/or references to avoid duplication of efforts. The recommendations, if related to exposure control methods, should be made in consultation with management and workers' representatives if necessary.

The OH survey report is a document that must be completed in accordance with the retention requirements of the company and/or the general legislative retention time of 30 – 40 years. Other OH documents that should be kept are: chemical and physical inventories with qualitative assessment; work histories; homogeneous exposure group and other OH documents that, together with health surveillance and biological monitoring data, can serve future epidemiologial or legal needs.

3.7. Exposure Control Methods

3.7.1. General Concepts

The most important function of a sound occupational health program is controlling and reducing exposure to hazardous agents to acceptable levels as part of risk management. The entire function consists of the selection and application of the most appropriate control measure and subsequent verification of its effectiveness.

Even if he is not directly responsible, the specific knowledge and experience of an occupational hygienist, particularly in certain control methods [e.g., industrial ventilation, personal protective equipment (PPE)], can contribute significantly to the success of the entire process. When conclusions drawn from qualitative and quantitative assessments (see Fig. 2) indicate that reduction of exposure is necessary, a number of factors should be considered by management in selecting the most appropriate method. Such factors should include urgency, cost-effectiveness, reliability, maintenance, and comfort of employees. Methods of exposure control can be divided into different categories. The order in which these categories are listed below corresponds to the hierarchical order of the risk manager's options; he should make his choice in line with good OH practice and in the spirit of current legislation.

1) Substitution (e.g., replacement of a toxic substance)
2) Containment (e.g., total enclosure)
3) Removal at source (e.g., local exhaust ventilation)
4) Administrative/procedural (e.g., reduced length of exposure)
5) Personal protective equipment (e.g., dust mask)

The above approach is based on the fact that elimination of exposure should be considered first, while PPE should be adopted as the last line of defense when it is neither possible nor practical to use any of the other methods. Using a material with better toxicological properties or different emission characteristics is clearly the best method of controlling exposure, although this is generally quite difficult because it requires extensive research and investment.

Control by containment means enclosing the process so that the characteristic emission of the substance cannot reach the worker. An automated feed system in processes and glove boxes in labs are typical examples. Removal at source normally implies the use of a local exhaust ventilation (LEV). The principles behind control of exposure by LEV are as follows:

1) Design the maximum degree of enclosure around the operation that still allows the work to be done efficiently. Decide on the necessary capture velocity to entrain emissions at the remaining enclosure opening (e.g., 0.5 m/s for vapors released into still air).
2) Calculate the necessary volume flow rate to achieve the required capture velocity.
3) Design, install, test, and maintain the system.

3.7.2. Personal Protective Equipment

Where it is not feasible or practical to adopt one of the other methods, including procedural measures, personal protective equipment (PPE) must be considered. Management has the responsibility to ensure that correct PPE is available and used, while workers must ensure its proper use. PPE includes a variety of devices for head, eyes, face, hands, ears, body, feet and lungs, providing protection against a wide variety of workplace health and safety hazards (chemical, physical, mechanical, biological, electrical, falls, fire, etc.). A sound program for the proper use of PPE taking into account its limitations, should be established and should address in general the following points:

1) Identification of health and safety conditions and hazards

2) Selection of the most appropriate PPE types
3) Procedures for use, storage, cleaning, maintenance, and disposal
4) Emergency procedure and use of PPE
5) Medical fitness and physical stresses
6) Education, training, and retraining of wearers
7) Inspections
8) Documentation

The Commission of the European Community (CEC) has promulgated a directive (89/656/EEC) which lays down minimum requirements for PPE used by workers at work. This directive, together with related CEC brochures and, above all, the standardization of technical specifications for PPE in CEN standards will harmonize manufacturing, selection and proper use of PPE in the EU countries, which up to now was regulated by national standardization schemes.

The safety officer normally administers the entire program. However, OH skills and knowledge are particularly significant when adequate respiratory protection and skin protection from chemicals are to be assured during routine tasks, as well as during special emergency operations.

The definition of the most suitable types of respirators derive from the analysis of the hazards and the assessment of risks to personnel, and then comparing merits and limitations of the various types and classes available (air-purifying respiration, air-supplying respirators, tight or loose fitting face piece, negative or positive pressure mode, escape only, etc.)

Consideration of the nominal protection factor (PF) assigned to a certain class of respirator, the required level of protection, the specific face-fit of the wearer, etc. are very important for an appropriate selection and are vital in critical conditions when personnel with facial hair may also be involved.

The protection factor is the ratio of ambient concentration outside the respirator to that inside the respirator facepiece. Multiplying the PF by the OEL of the substance under consideration gives the maximum use concentration.

The selection of adequate protective clothing as a barrier against chemical penetration also requires specialized knowledge. Interpretation and judgment of extensive and often conflicting data from suppliers and literature on chemical permeation testing is needed, together with considerations of comfort and hand sensitivity.

3.8. Physical Agents

Various physical agents may be encountered in the workplace. Some, such as noise and vibrations, are very diffuse and affect many workers; others, such as compression and decompression, are typical of work environment where the atmosphere is not at normal pressure and temperature (e.g., divers).

Other physical agents include:

1) Stress due to heat and cold.
2) Sources of intense optical radiation, such as ultraviolet and infrared lights and lasers, which may produce eye and skin damage.
3) Electromagnetic fields, for which certain chronic health effects are still under investigation.
4) Ionizing radiation, typical of the nuclear industry and in various other applications (e.g., medicine, gauging equipment). Exposure to ionizing radiation causes damage to living cells.

Each physical agent has its own characteristics, mode of entry, health effects, etc., and therefore requires a specific approach and technology if it is to be assessed and controlled in the workplace. Specialized literature, international guidelines, and legislative requirements for physical agents have been established in some countries.

Occupational exposure to *noise* is by far the most diffuse, most widely studied, and has the greatest impact of all physical agents. It has been estimated that $> 13 \times 10^6$ workers in the EU states are exposed to excessive noise for most of their working time. Although for many years noise at work has been known to cause hearing loss, it was only during the last three decades that major scientific studies have allowed full understanding and quantification of relationship between noise exposure and risk to the human auditory system.

Noise, or an unwanted sound, is described as oscillations in pressure above and below atmospheric pressure which evoke an auditory sensation. Prolonged exposure to sufficiently high levels of noise can produce permanent damage

to the hearing mechanism. Other nonauditory effects (e.g., physiological) can be attributed to noise exposure at lower levels. Such effects are less well-known and also occur in many human leisure activities. The level of exposure to noise for which there is international consensus that the risk of hearing damage is limited and at which most legislations set the limit for 8 h of exposure is 85 dB (A) as a time weighted average. Impulse noise should also not exceed 120 dB at any time.

Assessment of noise exposure is the first important element of a complete hearing conservation program. The other integral steps are: technical measures and abatement techniques; administrative measures (reducing time of exposure, area delimitation, noise specifications, etc.); selection and use of hearing protection (various types of ear muffs and ear plugs); education or training of personnel; and preliminary and routine audiometric testing to check the degree of hearing impairment.

There are two basic methods of assessing noise exposure. The first consists of fixed-position measuring of noisy areas or equipment by a sound level meter which can also measure impulse noise, and calculating the total noise exposure, taking into account the time spent by the worker in each measured area. In the second method, the worker has a personal audiometer, capable of continuously monitoring noise levels throughout the working shift. The use of both techniques at appropriate intervals can be considered the most effective approach for assessing noise exposure.

3.9. Communication and Training

The final essential element of an OH program is providing information, training, and education in the field of IH and hazard communication for personnel at all levels. This is a basic requirement of all health and safety legislation. Regular communication of accomplishments, performance, new relevant information, issues, concerns, and regulatory development to management is needed to maintain high awareness and support.

Potentially more exposed personnel who operate equipment and handle materials can contribute with personal control and attention in minimizing exposure if they understand the nature of the hazard and how work procedure affects emission and contamination.

OH training is normally done in cooperation with the supervisor and other departments (e.g., safety and medical) as part of the initial routine health and safety training. Topics that should be included are:

1) Physical, toxicological, and warning properties of substances and their possible consequences and health effects upon exposures
2) Ergonomic factors and recommendations
3) Results and interpretation of occupational exposure assessment
4) The proper use and limitations of PPE

Many specific sources of such information are available at international and national level. The most appropriate approach and method to provide such training should be designed according to the background and level of education of the people it is intended for.

Verification of the effectiveness of this program, for example, by means of a questionnaire, should be considered. Training records should be made according to legislative requirements and practices.

3.10. Industrial Hygiene in the United States

Although some education programs existed previously, the first industrial hygiene section was organized by the Public Health Association in 1914.

In 1915 the U.S. Public Health Service organized a division of Industrial Hygiene and Sanitation. The *Journal of Industrial Hygiene* was first established in 1919 and in 1925 became the *American Industrial Hygiene Association Journal*. The present Harvard School of Public Health had a Department of Industrial Hygiene in 1922. Chemists, engineers, physicians, toxicologists, and other specialized graduates have applied their knowledge to the growing scientific profession of industrial hygiene. The American Hygiene Association was organized in 1939. Since then improvements in plant design, machine design, and plant layout have seen the worker come to expect a safe workplace, in

part because of the activities of the industrial hygienist.

With progressing industrial and workplace safety, today's industrial hygienist is still involved with control of dust hazards, skin irritants, noise levels, personal protective equipment, classification of hazards, and training. However, with additional data, better monitoring methods, and more precise measurements, chronic occupational problems are now of greater importance. Information has been developed on chemical exposure limits in workplace air by several organizations such as the National Institute for Occupational Safety and Health (NIOSH) with recommended exposure limits (RELs). The Occupational Safety and Health Administration has proposed permissible exposure limits (PELs) for several hundred chemicals. If accepted by the legal process, these could become regulatory standards. As with all OSHA standards, the PELs are being strongly challenged in the courts.

The American Conference of Government Industrial Hygienists (ACGIH) have developed guidelines or recommendations called threshold limit values (TLVs). These recommendations and guidelines all assist the industrial hygienist with the control of potential health hazards. In addition, for different working conditions, these values are expressed as time weighted averages (TWAs) and as threshold limit values- ceiling (TLV-C) for exposures not to be exceeded even instantaneously.

All of these guides and values represent levels to which nearly all workers can be exposed without adverse health effects. With the help of data automation, the industrial hygienist sets up sampling monitoring and analytical programs to measure and correct exposure conditions. Physical agents such as temperature, stress, radiation, vibration, and pressure variations are more recent areas of study where practicing industrial hygienists can continue their strategy of occupational safety.

Today's industrial hygienist must draw on the knowledge of a broad range of disciplines in the medical, biological, and technological fields to prevent work strain from reducing performance or becoming pathological. The primary objective is to provide a workplace free of recognized hazards.

4. Occupational Medicine

4.1. Health Surveillance [29–32]

One of the main goals of occupational health care is to protect workers from harmful effects due to work or the working environment.

The various means that can be used to achieve this goal can be summarized under the heading of health surveillance.

In general terms health surveillance comprises four sequential steps:

1) Monitoring/measuring
2) Evalution
3) Interpretation
4) Corrective actions

The first step in health surveillance consists of measuring parameters of exposure and uptake or effects. Secondly, the results must be evaluated and interpreted with respect to the question of whether any health impairment exists or is to be expected.

When it is concluded from the monitoring results that inadmissible exposure or uptake is occurring, corrective measures should be taken to prevent further health risks. Which measures have to be taken depends on the particular situation and is decided by a case-to- case approach.

Health surveillance in the framework of occupational health care may be aimed at:

1) Specific occupational branches, such as health care services, construction and building industry, chemical industry
2) Special occupational cohorts, such as busdrivers, railway personnel, operators in the process industry
3) Particular occupational diseases, such as hepatitis in nurses and skin conditions in bricklayers
4) Occupational health problems due to exposure to particular biological, physical, or chemical agents

The discussion in this chapter is restricted to examinations dealing with potential hazards from occupational exposure to chemicals.

4.1.1. Monitoring

Monitoring is "the repetitive and continued observation, measurement and evaluation of health and/or environmental or technical data for defined purposes, according to pre-arranged schedules in space and time and using comparable methodologies for sensing and data collection" [30]. This description is still valid.

The most essential criteria for reliable monitoring procedures are:

1) The activity should serve a defined objective
2) Continuous or repeated observation
3) Comparison of the data observed with a reference level [31]

Monitoring implies a multidisciplinary activity in testing, watching, and observing situations and/or persons. In the occupational setting this means examinations of the working environment and/or the workers.

Which mode of monitoring will be preferred depends primarily on the goal of the examination and a number of factors, which are discussed below.

Monitoring Strategy. Before any health surveillance action is started, a decision has to be made about the nature and design of a prearranged schedule, adopted to meet a defined objective. This decision depends mainly on the answers to a number of questions to be posed, certain criteria to be met, and the availability of appropriate monitoring methods.

The most important and crucial questions deal with the aims and means of a health surveillance program:

Why carry out an examination? What are the objectives and what do we want to know? Is exposure of workers actually taking place?

The answer to these key questions generally implies the answers to the next questions.

Who must be included in the surveillance program? What is the actual population at risk? Which criteria are valid for assessing this risk group?

What will be measured and monitored?

The answer to this question presupposes some knowledge about the nature of the exposure.

What is the most suitable way and the most relevant place to monitor and which parameters need to be measured?

The answer to this question presupposes fairly good knowledge of the biological fate of a chemical in the human body.

Which sampling procedures and analytical methods are available and suitable in a particular situation?

When and how often must monitoring be performed?

In some countries detailed guidelines or strict rules are given for the methods and frequency with which health surveillance is to be performed. In Germany this is regulated by the "Berufsgenossenschaftliche Grundsätze für Arbeitsmedizinische Vorsorgeuntersuchungen" [31]. Guidelines are given in the United Kingdom by the Health and Safety Executive (HSE) and in the United States by the Occupational Safety and Health Administration (OSHA).

Monitoring Criteria. Apart from the above mentioned questions, some criteria must be met for proper design of a health surveillance program.

In 1975 WHO issued criteria for periodical medical examination that are still valid. The most important of these criteria are:

1) It should not involve undue expenditure of time, equipment, or staff.
   In other words, the cost and discomfort for the individual and for society should be in balance with the health benefits to be expected.
2) It should not be inconvenient to workers.
   A liver biopsy might be considered to be the best diagnostic means in a particular situation. But, as this operation could be fatal, one is very reluctant to perform it for the medical surveillance of healthy people.
   This criterion can also play a role in the choice of biological medium. Thus taking a blood sample or collecting a 24-h urine sample could be experienced as difficult and inconvenient.
3) It should be an early reversible predictor before overt health effects are impending. Surveillance activities which can be classified under biological monitoring and biological effect monitoring meet this criterion.
4) There should be a quantitative relationship with exposure and with health risk.

For most effects caused by chemicals, a dose – response relationship exists. Measuring a particular parameter is only significant when this dose – response relation and/or dose – effect relationship can be expressed numerically. Preferably, the effect measured should have a steep dose – response curve which enables the intensity of effects to be more easily distinguished.

For proper evaluation and interpretation, valid reference data are essential.

Figure 3. Instruments for health evaluations of workers
EM = Environmental monitoring; BM = Biological monitoring; BEM = Biological effect monitoring; PME = Periodical medical examination
MAC = Maximum allowed concentration; TLV = Threshold limit value; BAT = Biologische Arbeitsstofftoleranz; BEI = Biological exposure indices

A very important criterion is that the tests should have high validity and effectivity.

Thus the aim is the highest possible specificity and sensitivity. Low sensitivity leads to an unsatisfactory number of false negatives (positives that wrongly score negative). The higher the specificity of a test is, the lower is the number of false-positives.

An essential condition for performing meaningful health surveillance programs for workers is that the management responsible is prepared to improve working condition if this is indicated. Also employees must be willing to improve their working habits and hygiene when necessary. If these requirements are not met, any health surveillance program is completely redundant and a waste of time for everyone involved.

Modes of Monitoring. The following modes of health surveillance can be distinguished:

Estimation of the health risk:
- Environmental monitoring (EM),
- Biological monitoring (BM),

Estimation of the state of health:
- Biological effect monitoring (BEM)
- Periodical medical examinations (PME).

In Figure 3 a scheme is given of these "instruments" for health evaluations.

These different monitoring methods can be exemplified on the basis of lead exposure.

When workers are exposed to lead fumes or dust, the following can be investigated:

1) The concentration of the fumes or dust in the working area (environmental monitoring, EM).
2) The content of lead in blood or urine of the exposed workers (biological monitoring, BM).
3) Indications of biological changes in blood production by measuring the content of δ-aminolevulinic acid dehydrogenase (δ-ALAD) or zinc protoporphyrine (ZPP) in the blood, or δ-aminolevulinic acid in the urine. This method is known as biological effect monitoring (BEM).
4) Indications of impaired health by physical medical examination of symptoms and signs of specific adverse health effects: anemia, lead line on the gums, abdominal cramps, obstipation, wrist drop, impaired renal function, and blood changes.

Environmental monitoring (EM) in this context means measuring exposures in the air at the workplace. These measurements are generally specific for a defined chemical. EM is used to determine the intensity of exposure, expressed as the concentration of a single chemical or group of chemically related compounds in the working environment.

However, exposure to a chemical or group of chemicals, does not necessarily mean that uptake into the human body will happen or has already taken place. Whether, in what way, and to what extent uptake results from exposure depends on a number of factors.

Air sampling close to the mouth and nose of an individual gives the best reflection of the actual nature and intensity of the chemicals inhaled during work. This type of EM is called personal air sampling (see Section 3.6.6).

In biological monitoring (BM) a chemical compound or one of its metabolites is determined in a biological medium, mostly urine or blood. BM can be regarded as a person-related, specific measurement of so- called biomarkers, which reflect the internal burden of a compound in the human body, irrespective of the route of entry.

Therefore, BM is a relevant method of health surveillance when individual screening is the goal. However, when it is intended to check or to control the working environment, environmental monitoring is the first method of choice. BM is discussed in more detail in Section 4.2.

4.1.2. Periodical Medical Examination

Periodical medical examination (PME) is the periodically repeated medical examination of individuals for health effects that may be related with their work or working circumstances. The main aim of these examinations is to detect early, reversible (pre-)clinical signs of health impairment.

PME is individual-related and aimed at the detection of nonspecific anatomical and/or functional disturbances of organs or tissues, irrespective of the cause.

Besides occupation, a number of intrinsic and nonoccupational extrinsic factors, including eating, drinking and smoking habits, may influence the nature and intensity of health effects. This means that in most cases it only can be estimated or inferred indirectly from occupational histories that a specific chemical is the causative agent.

A periodical medical examination implies the drafting of a medical history, a physical examination and, when indicated, additional tests.

Elements of a periodical medical examination are:

Medical History
- current state of health
- previous ailments
- medication
- life style

Physical examination

Additional examinations
- blood or urine tests
- lung function
- neurological/electrophysiological
- chromosomes
- sperm

Example 1. The presence in blood of a particular quantity of carbon monoxide bound to hemoglobin (CO-Hb), may be caused by the exposure and uptake of carbon monoxide itself, but can also be due to exposure and uptake of the solvent dichloromethane. Heavy smoking has to be considered as a confounding factor.

Example 2. A large number of pesticides, chiefly organophosphates, act in the body by blocking the enzyme acetylcholinesterase, which regulates nerve – muscle action by hydrolyzing acetylcholine; thus, excessive amounts of this muscle stimulator accumulate. However, the clincal symptoms of inhibition of this enzyme do not indicate which particular acetylcholinesterase inhibitor is the causal agent.

Example 3. Headache may be caused by a large number of etiological factors, unrelated to any occupational activity. But even when a relationship with occupation cannot be ruled out, it is often difficult to determine whether this symptom is caused by the exposure and uptake of a neurotoxic organic solvent or is due to mental stress at work.

Example 4. A disorder of liver function may be of bacterial, viral, or chemical origin. But even when it is obvious that it has been induced by a chemical agent, it may have been the result of a lifelong excessive drinking of alcoholic beverages during leisure hours, the use of particular pharmaceuticals, or exposure to and uptake of chlorinated hydrocarbons during work.

In the early days periodical medical examination of individual workers consisted almost entirely of detection of clinically apparent symptoms. Nowadays, increasingly subtle diagnostic methods are used, enabling the physician to detect early reversible effects which may be considered to be not yet adverse or pathological.

A number of early effects can be regarded as forming part of the physiological defense mechanism of the human organism. Zielhuis and Henderson [32] use the term biological effect

monitoring for this kind of examination and defined it as: "the measurement and assessment of early biological effects, irrespective of their significance to health, in exposed workers and health risk compared to an appropriate reference."

However, the line between physiological and pathological effects is often hard to draw because the distinction may be indistinct.

For some effects it is still unclear whether they should be considered adverse or harmful, or neither. Examples of effects that are still under discussion between experts are enzyme induction (see Section 4.5) and some electrophysiological phenomena in nerves or muscles.

Apart from whether a particular effect can be regarded as a biological or pathological response of the human organism, there is another crucial criterion for deciding whether a specified effect is tolerable or not. This criterion is the reversibility of an effect after exposure to the causative chemical agent ceases.

Sometimes it is a matter of academic or political dispute whether a particular person-related measurement is called BM or BEM. Although this does not change measurement method, it can have a major impact on the establishment of biological limit values and the setting of standards.

For example, the determination of carbon monoxide – hemoglobin complexes in the peripheral blood may be regarded as an indication of the total body burden of CO (which is BM), but also as a parameter of BEM because it reflects the proportion of hemoglobin that is blocked and not available for oxygen transport from the lungs to the tissues.

4.1.3. Evaluation and Interpretation of Data

The most important step in the entire health surveillance (HS) process is the evaluation and interpretation of the test results.

For interpretation of the monitoring results, the data must be compared with reference data. Therefore, it should be clear before starting any health surveillance program which references can and should be used.

The availability of valid reference data is an inherent part of the considerations during the structuring of a surveillance scheme.

Evaluation. Before the test results of a health surveillance examination can be interpreted properly, it should be determined whether the collected data are appropriate and reliable with respect to health.

It is essential that relevant and proper methods be used with appropriate sensitivity and specificity, and that they be performed with correct sampling, storage, and analysis. For this reason some method of quality control for accuracy and precision should be incorporated [e.g., good laboratory practice (GLP) or round robin tests].

For intra- and interindividual comparison with previous test results, adjustment of data may be indicated. Thus, data from urine samples have to be adjusted for specific gravity or creatinine excretion.

Another consideration is whether – and if so which – intrinsic and extrinsic factors could have confounded the results. These factors can include smoking, drinking, diet, medication, and others.

For correct evaluation and interpretation proper choice of reference data is essential. The reference data used depend on the objectives of the HS program and the conclusions to be achieved: Do we have to make comparisons with figures for the general national or local population? Will we draw conclusions for groups of workers or individuals? Do we want a cross-sectional impression of the current overall health state of a group of workers or a longitudinal view of the progression of specific parameters throughout the years for individuals or groups of workers? In longitudinal studies, the current data can be compared with results from previous examinations. For individual workers, reference data from the pre-employment examination may be of value. When no reliable reference data are available, the best estimate should be made from epidemiological and animal studies (see also Section 4.5).

Reference data for physical (pre-)clinical symptoms and signs of impaired health depend on the knowledge and skills of the physician who performed the periodical medical examinations. Data from laboratory tests for estimating the state of health depend on the methods used and the specificity and their sensitivity.

As HS is meant to determine preclinical reversible signs in healthy people before these

must be considered adverse, in general the laboratory tests have to be more sensitive and the reference data more subtle than those used in hospital for patients with impaired health.

For a number of chemicals, occupational threshold limit values for exposure are set. For a limited number of chemicals biological limit values for uptake have also been established. In the United States biological exposure indices (BEI) are used, and in Germany Biologische Arbeitsstofftoleranzwerte (BAT values). For details, see Sections 3.6 and 4.2.

To ensure that all essentials are considered, the use of a checklist for the evaluation of health surveillance data is helpful:

Methods and sampling
- appropriate (sensitivity, specificity) ?
- correctly performed?

Adjustment for correct interpretation

Confounding factors?
- intrinsic (age, enzyme deficiencies, etc.)
- extrinsic (life-style, pharmaceuticals, etc.)

Reference data available?
- individual
- group
- general population

Occupational limit values available?
- guideline/advisory
- legal/obligatory

Interpretation. Once the data have been evaluated it has to be established whether the HS results indicate impairment of health.

Universally fixed "normal" values do not exist, because geographical, ethnic, age, and gender differences may be apparent. Even between individuals within a quite homogeneous group of people and, even within the same individual, fluctuations can be found, due to the range of physiological variability. Differences in basic body burden of individuals may be due to extrinsic factors such as life-style (eating, smoking, etc.) and leisure activities.

With respect to pre- clinical reversible biological effects, it has to be considered whether these are medically acceptable or not. This is completely a matter of professional knowledge and skills. The final decision however, on what is tolerable, is not only a medical but also a political issue and will include a balance between technical and economical feasiblity and acceptability by society. This can differ from country to country and between social groups.

4.1.4. Reporting Health Surveillance Results

After completion of the health surveillance program, it has to be decided to whom, when, and which information about the results will be given.

The workers involved as well as the responsible management must be provided with the relevant information.

With respect to BM and BEM data, it should be emphasized that these monitoring methods are person-related. This implies that individual workers have the right to be informed of their own personal test results. To enable the worker to put these data into perspective and to understand the uses and limitations of BM, some basic information on the dose – effect relation, reference data, etc., should be provided as well. The individual data must be considered as confidential and only accessible to the worker and physician involved. They are only to be provided to workers' representives or management with the explicit consent of the individual worker.

The employer is given an anonymized compilation of the group data, to allow him to judge the working conditions and the effectiveness of preventive measures already taken.

4.1.5. Corrective Actions

The results of health surveillance indicate whether corrective preventive actions are necessary or advisable.

These actions may be restricted to individuals in a group who showed aberrant and unwanted signs of chemical overload or a health threat, compared with the group mean and/or the average in a group of nonexposed people.

It must be investigated why these individuals differ from the others: are they at risk due to higher exposure or uptake, or are they subject to individual hypersensitivity?

Individuals with abnormal HS results should be temporarily withdrawn from their work until the figures are back to normal. Sometimes, permanent withdrawal from specific work conditions has to be considered; for instance, after (pre-)clinical signs or symptoms of asthma due

to isocyanate exposure or when skin conditions due to a susceptibility for sensitizing agents have been diagnosed.

Moreover, certain medical conditions unrelated to work may be incompatible with certain job activities. Restrictive and obstructive lung diseases prohibit exposure to irritating gases, vapors, and dusts. Exposure to a number of chemicals is contraindicated for workers with functional liver and kidney disorders.

When the group mean of the examined workers appears too high compared with nonexposed people, or higher than the group mean in a previous examination, measures at the job or working environment level should be considered.

A critical survey of current work systems and practises can often lead to improvements which are simple and cheap to achieve and lead to reduction of emissions, exposures, and uptake.

As has been mentioned before, TLV values may be not always protect every worker from adverse health effects under all circumstances. Therefore, for each group of workers and for each specific working condition, a critical appraisal should be made about the time-weighted average concentration of chemicals that can be considered to be safe in a defined situation. This holds too for chemicals that are not included in official lists of TLV values.

A reduction of emission can be achieved by substitution of potentially toxic chemicals with less hazardous ones, or modification of manufacturing processes, technology, and installations. Also changes in procedures and organization can improve the working conditions.

The intensity of uptake can be reduced by personal protective equipment (see Section 3.7.2).

4.2. Biological Monitoring [33–38]

Biological monitoring (BM) is one of the methods for the health surveillance of individual workers.

BM can be described as: "Measurement and assessment of workplace agents or their metabolites either in tissues, secreta, excreta or any combination of these, to evaluate exposure and health risk, compared to an appropriate risk" [33].

4.2.1. Basic Considerations

BM is a person-related specific way of monitoring to estimate the health risk due to exposure to a particular chemical or group of chemicals. The aim is to obtain a measure of the internal burden of a defined chemical in the body of an individual after absorption, irrespective of the route, time, or duration of intake. BM is especially important for chemicals that are readily absorbed through intact skin, such as benzene, acrylamide, dimethylformamide, dinitro-*o*- cresol, and methyl parathion.

With respect to health surveillance, BM is far more relevant than environmental monitoring, which only reflects the possible exposure by inhalation during work.

When appropriate methods are available, BM is always the method of choice for the health surveillance of individual workers, because it reflects the individual uptake by all routes and is almost always substance-specific.

Thanks to steady progress in knowledge about the biological fate of chemicals in the human body and improved specific and sensitive analytical methods, there is a growing number of chemicals for which BM methods have become available.

Although a specific response is measured by means of BM, it is not a reflection of the way the chemical has entered the body. Mercury in the urine can be caused by ingestion of metallic mercury, inhalation of mercury vapor, or transdermal and transmucosal absorption of an organomercury compound. Carbon monoxide, determined in the blood, might be due to smoking, gas fumes in the home due to poor ventilation, occupational exposure to carbon monoxide in a blast-furnace plant, or stripping paints with methylene chloride. Hippuric acid in the urine might be due to the metabolism of toluene taken up during work or to digestion of various food constituents.

As BM always reflects a compilation of past exposures, it is generally not suitable for determining peak exposures during work. It also will give no indication of contact of skin or mucous membranes with chemicals that are not absorbed through them, although they may exhibit local effects.

Moreover BM results must be evaluated with care. Figures that exceed certain reference val-

ues may not necessarily be considered as harmful to health and therefore unacceptable. And levels below reference values may not always be acceptable for every individual or in all circumstances.

4.2.2. Prerequisites

BM can only be used properly when the following conditions have been met:

1) Before any measuring strategy can be designed the aims of health surveillance must be defined. For example: Are we interested in current or past exposures? Do we want individual figures or group means? Only when these conditions have been met is the design of a proper and sensible BM scheme possible. In general this means that in a BM program adapted to the conditions chosen, the most suitable parameter should be measured in the most suitable biological medium in the right way at the right moment in the right population.
   In general, determination of concentrations in blood better mimics current exposure, whereas urine samples give a better indication of past exposures.
2) As the parameters to be measured are intended to the way the human body deals with the chemical involved, relevant knowledge of pharmacokinetics, uptake, distribution and the route and rate of elimination is essential.
3) To consider possible health effects additional information about a quantifiable relationship between the parameters to be measured and apparent clinical or biological effects is needed.
4) Appropriate and reliable analytical methods must be available, and must meet the requirements for sensitivity, specificity and reproducibility.
5) The considerations for a proper BM surveillance scheme are the same as for other methods of health surveillance (see Section 4.1).

4.2.3. Biological Media

In principle, various media can be used:

1) Body fluids such as whole blood, plasma, and serum
2) Body tissues, e.g., hairs, nails, teeth, fat tissues, placenta
3) Excreta: urine, sweat, saliva, feces, expiratory air, mother milk.

However, the choice of biological medium depends upon a number of considerations, including aims, feasibility, availability of proper analytical methods, specificity, sensitivity, and cost.

Urine and blood are still the prevalent media in common practice. The advantages and disadvantages of the most frequently used media are discussed below:

Urine is the most suitable and easy obtainable test medium for water-soluble chemicals or metabolites that are excreted in the urine. It can give an impression of the average uptake in the past.

A drawback of the determination of chemicals in the urine is that the quantity and composition of the urine varies over a 24-h period, as does the content of the chemical to be determined. Sampling over a 24-h period overcomes this disadvantage to some extent, but it is technically difficult to achieve. For correct interpretation of the analysis of one single sample a correction for specific gravity or creatinine excretion is indicated.

Blood is the most important means of transport and distribution for chemicals in the body. Biomarkers determined in blood reflect the circulating quantity of the chemical itself or of a metabolite. Based on the half-life of a chemical in the body, the data give an impression of recent uptakes, and sometimes peak exposures can even be distinguished.

Some chemicals can be found in the red blood cells (e.g., chromium) whilst others are bound to plasma proteins. Chemicals such as carbon monoxide, hydrogen sulfide, cyanides, and nitrites form complexes with hemoglobin.

Sampling of blood by venopuncture may often act as an emotional barrier for people to cooperate.

Expiratory air is especially useful for volatile compounds which are metabolized slowly, are poorly soluble in body fluids, and are largely exhaled. Sampling and analysis of expiratory air is often simple. The interpretation is complicated by inter-individual differences in respiratory patterns.

Analysis of chemicals in *faeces* is suitable for chemicals that are taken up orally or are excreted into the intestines via the biliary system. The interpretation with respect to exposure or contact and to health is difficult or even impossible.

For most chemicals, determination in hair, nails, saliva, mother milk, etc. does not provide additional useful information with respect to health risks for exposed people. Determination of chemicals in mother milk may give an indication of the amount that could be taken up by breast-fed babies.

4.2.4. Biological Occupational Limits

For a number of chemicals, reference values are available for some relevant biomarkers. Until now, only in Germany and the United States are lists of this type of limit value published. The figures may differ between these two countries due to differences in definition.

In the United States biological exposure indices (BEI) are published by the American Conference of Governmental Industrial Hygienists [34]. These indices are intended as guidelines for evaluation of potential health hazards. They "represent the levels of determinants which are most likely to be observed in specimens collected from a healthy worker who has been exposed to the same extent as a worker with inhalation exposure to the TLV."

The German BAT value (tolerated biological value for occupational exposure to chemicals) refers to the maximal concentration of a chemical or metabolite which, based on current knowledge, does not impair the health of individual workers [35].

For the current values refer to the lists mentioned in the literature reference list. In Table 1 parameters for BM and BEM are given for some chemicals.

Except for inorganic lead, no biological exposure limits are set as legal standards. Until now they only serve as guidelines and recommended reference data in the health surveillance of workers.

For inorganic lead, a CEC Directive was adopted in 1982, which all Member States are committed to incorporate in the national legislation.

The Directive sets action levels and limits both for lead in air and for biological indicators.

Based on the CEC Directive, a resolution on lead ("Loodbesluit", 1988) came into force in The Netherlands with the same action levels and limits. However, the Dutch Expert Commission for Occupational Standards recommended a biological acceptable limit of 400 µg lead/L blood for men and 300 µg lead/L blood for women.

For health surveillance of workers exposed to lead, it is recommended to start with a simple determination of ZPP (zinc protoporphyrin) in blood with a hematofluorometer. When the ZPP content of blood exceeds 20 µg/g hemoglobin, additionally PbB should be determined.

Action levels:
PbB > 400 µg/L $\longrightarrow$ information of workers
PbB > 500 µg/L $\longrightarrow$ full application of the directive, including obligation for periodical medical examination
Limit values:
PbB max. 700 µg/L
PbB 700 – 800 µg/L is acceptable when:
ALAU > 20 mg/g creatinine
ZPP > 20 µg/g hemoglobine or,
ALAD < 6 Eur. Units

where PbB = lead in blood, ALAU = δ-amino-levulinic acid in urine, ZPP = zinc protoporphyrin in blood, ALAD = δ-aminolevulinic acid dehydrogenase in blood.

4.2.5. Interpretation of Biological Monitoring Data

From the point of view of health, BM is much more relevant than EM. Even when the relation between BM and EM results is fairly well known on a group basis, this relationship may differ significantly on an individual basis.

Therefore, BM programs should be performed under the supervision of an (occupational) physician. Interpretation of BM data for groups or individuals should be based on medical-toxicological expertise. The physicians involved must have the expertise to evaluate the data with respect to intrinsic and extrinsic individual factors which might explain interindividual variability, in order to come to the correct conclusion about the state of health of the individuals under surveillance.

Table 1. Biological monitoring and biological effect monitoring for some chemicals

Compound	Biological monitoring		BEI∗∗	BAT∗∗	Biological effect monitoring	
	Parameter	Medium∗			Parameter	Medium∗
Acetone	acetone	U				
	formic acid	U				
	acetone	B				
	acetone	E				
Acrylonitrile	thiocyanate	B				
	acrylonitrile	B				
Aniline	*p*-aminophenol	U	X		methemoglobin	B
	aniline	U		X		
Antimony	antimony	U				
Arsenic	arsenic	U				
Benzene	benzene	B			leucocytes	B
	benzene	E	X		hemoglobin	B
	phenol	B	X			
Bromine (salts)	bromide	U				
Butylglycidyl ether	butoxyacetic acid	U				
Cadmium	cadmium	U	X		β-microglobulin	U
	cadmium	B	X			
Chloroform	chloroform	E				
	chloroform	B				
Chromium	chromium	U	X			
Cyanides	thiocyanate	U			cyanohemoglobin	B
	thiocyanate	B				
	cyanide	B				
2-Ethoxyethanol	2-ethoxyacetic acid	U		X

	xylene	B		X		
Carbon monoxide	carbon monoxide	E	X		CO−hemoglobin	B
	carbon monoxide	B	X	X		
Carbon disulfide	thiothiazolidine-4-carboxylic acid	U	X			

∗ B = Blood; U = Urine; E = Expired air. ∗∗ BEI = Biological exposure index (ACGIH); BAT = Biologische Arbeitsstofftoleranz.

Among other things, inter-individual differences in enzyme configurations can influence the possible health effects of chemicals. For instance, due to a difference in biotransformation, people with inherited low acetylating enzyme profiles ("slow acetylators") are at greater risk of intoxication with methemoglobin forming compounds such as aniline or nitrobenzene than those who have large amounts of the acetylating enzyme.

Note, that BM cannot always replace EM, and sometimes a combination of both methods is indicated. Especially when the test results from BM exceed the reference data or recommended biological occupational limits, EM is indicated to estimate whether air levels at the work place are responsible, or other work-related factors such as poor hygiene at work, or endogenic or nonoccupational exogenic factors must be considered.

This question is particularly important for the decision whether corrective changes in the working conditions must be made or not. BM may also serve as a check for the effectivity of measures taken to reduce the exposure of workers.

4.3. Occupational Epidemiology (General references: [39–43])

4.3.1. Introduction

Going back to ancient Greek roots, epidemiology can be defined as the science (*logos*) of what comes upon (*epi*) the people (*demos*).

In modern terms it should be understood as the study of the occurrence and patterns of disease in groups of people. Whereas daily occupational medical routine looks at individual persons, occupational expidemiology is concerned with groups or cohorts. The basic requirements

for any analytical epidemiological study are careful collection of relevant data, appropriate statistical analysis, and qualified interpretation of the results. The type of study chosen to answer a particular question should not only suit the size of the group under investigation but also the quality and quantity of data that can be obtained. Although occupational epidemiology can be regarded as one of several scientific instruments for the assessment of a particular occupational health hazard, it must be remembered that no epidemiological study can prove or disprove cause and effect relationships. How close to the "truth" a particular study will come largely depends on the quality of the study (i.e., the quality of the data), on careful performance of the study, and on expert interpretation of the results. The results should be interpreted in the context of the outcome of similar studies. Successful occupational epidemiological studies demonstrate the magnitude of risk associated with a particular level of exposure to a particular agent at the workplace.

4.3.2. Basic Requirements – Data Collection

4.3.2.1. Data on Exposed Individuals in the Study Group

For occupational cohort studies, data are needed to identify individuals in the cohort (e.g., full name, sex, ethnic origin, date of birth, personnel or social security number).

Also needed are data that connect these individuals to the cohort, such as date of entry into the company or plant where the individual is employed during the period of study, and where applicable, also the date of leaving employment.

For mortality studies the date of death or the vital status on the closing date of the study should be known. Also the cause of death must be known and it should be stated from which source (e.g., death certificate, autopsy report, etc.) this information was obtained.

For morbidity studies (concerning persons suffering from a disease) the date on which the key diagnosis was made should be known, as well as its diagnostic certainty (e.g., in the case of cancer whether the diagnosis was made by clinical means only or by histology of surgical material).

If other, confounding factors influence the occurrence of a disease (e.g., smoking in the case of lung cancer) then they must also be considered.

During data collection, it is essential to link personal data to occupational or work-environment data if a study on a specified occupational hazard is to make any sense. For subsequent statistical evaluation and publication, the data can be anonymized without any loss of quality to the study.

In many countries restrictive laws on medical confidentiality and/or data protection severely hamper the conduction of sound epidemiological studies.

Data may be very difficult to obtain when studies deal with exposures in the past because personnel files or occupational medical records may have been destroyed. In case of foreign labor many cases may be lost to the study because of workers having returned home.

In many countries death certificates are not available for occupational epidemiological studies; therefore, data on cause of death must be obtained by the best available means. If the study population is compared with the general population of the country by using the official death statistics, which are based on death certificates, then this differing source of information must be taken into consideration, as it can influence the result of the study.

For morbidity studies (e.g., the occurrence of certain types of cancers) the obstacles can even be greater. Fully functioning cancer registries, as well as national population registries, are often lacking. Some cancer registries contain little or no information on the occupational history of the cases or only include the last occupation. Even if all cancer cases were known in a particular population under study the comparison with another (e.g., the general population) would be difficult if not impossible. Thus it is not only important to very carefully collect data but also to validate the source from which they are obtained.

4.3.2.2. Technical Data on the Occupational Environment

The occupational environmental exposure of an individual worker stems from the local environment (the workplace), the activity performed

(the job), and the factors present such as chemicals or physical agents. It is thus essential that information on these items be available. For studies concerned with past exposure (retrospective studies) this may be very difficult. For example, the time between the beginning of exposure to a bladder carcinogen such as 2-naphthylamine and the development of a bladder tumor (the latency period) may be as long as 20–40 years. Quantitative exposure data may not be available after such a long period, or may never have existed. The only source of information may be the detailed occupational history taken from those persons who are still available for questioning by the occupational physician in charge of the study. In some cases an intelligent guess can be made with the help of the industrial hygienist about the exposure level.

For studies concerned with future exposure (prospective studies) occupational exposure recording systems should be established in production plants where a potential health hazard is present or suspected and should be linkable to the individuals working in that particular plant or production site. Two types of exposure data can be used: exposure information relating to the workplace or to the job. For some chemicals biological monitoring yields a third type of exposure data specific for individual workers.

Information on the Workplace. Descriptions of industrial processes and working conditions should be available and should be updated when changes occur. Lists of chemicals or raw materials should be available in an accessible and comparable form, indicating substances present by means of appropriately defined workplace codes (e.g., by the CAS code).

Records should be kept on the quantities used and produced. Exposure measurements at the workplace (ambient monitoring) should be based on standardized sampling and analytical methods, backed by quality control programs to confirm the validity of the data produced. Results of personal monitoring should be stored with cross-references to the individual concerned to permit dose – effect and/or case studies to be performed.

Information on the Job. Job exposure information can be obtained from data representative of the activity performed (job) as opposed to that of a particular workplace. For this an appropriate description of the job is necessary (job exposure profile), which should be exposure orientated. Wherever possible the job description should be complemented with job-specific exposure measurements. Problems arise when a worker cannot be assigned to one specific workplace (e.g., working in different parts of the production or doing maintenance work), when mixtures of several chemical substances are handled, or production and products change very frequently.

Biological monitoring gives information on individual exposure (inhalatory and skin absorption), and helps to identify exposed workers.

4.3.3. Descriptive and Analytical Study Types

Descriptive studies are concerned with the observation of the distribution and the progress of a disease in groups of exposed persons. They are limited to the determination of incidence (number of new cases occurring per unit time relative to the number of persons at risk), prevalence (the number of existing cases per unit population relative to the number of persons in the population at a certain point of time), or mortality rates for certain diseases.

Analytical studies are concerned with a hypothesis about causal (etiological) factors of the disease, developed from a descriptive study or from individual occupational medical observations. The purpose of an analytical study is to determine an association between a suspected causal or risk factor (e.g., a carcinogen) and an effect (e.g., the occurrence of a specific cancer). Under favorable circumstances the strength of this association can be quantified (the "power" of the study).

The several types of analytical studies are described below.

Cross-Sectional Studies. Cross-sectional (also called prevalence) studies concentrate on a defined population at a particular point in time. They are set up to determine prevalences of disease in the exposed and nonexposed groups. Cross-sectional studies are relatively simple and quick to carry out and may be used for preliminary testing of a hypothesis. But since they

merely examine new cases or drop outs they give rise to a selection effect.

Case Control Studies. In case control studies two groups of individuals are selected: the cases (suffering from the disease) and the controls (not suffering from the disease). The two groups are then compared with respect to present or past characteristics thought to be of possible relevance to the etiology of the disease. This type of study is always retrospective, i.e., the effects are already present at the beginning of the study. The conditions of exposure must therefore be reconstructed from the past.

A case control study has the advantage of being easily carried out in a relatively short time and does not need large numbers. Indeed, for the study of rare diseases this may be the only useful method. The great disadvantage, however, is the difficulty of collecting past data for both cases and controls. Interviewing cases in the knowledge that they are suffering from the disease may bias data collection, and it may be difficult to find appropriate controls.

Cohort Studies. The cohort study compares the incidence of a disease in two or more groups (cohorts) which are observed in parallel for a given period of time. An exposed group is composed of individuals with known exposure to a suspected risk factor. The control group is not exposed, but otherwise comparable for as many criteria as possible.

This type of study is also called longitudinal. It can be carried out in a prospective way, i.e., starting with apparently healthy individuals and observing them for a defined period. It can also be carried out in retrospective (historical) way, i.e., a study date is set from which the observation is retrospectively carried out to a starting date. For both types of cohort studies standardized rates of mortality or morbidity are used and compared with standardized rates of a suitable reference population.

Prospective studies have the great advantage of being more reliable and of better validity than retrospective studies, but they may take a very long time and be very costly. Retrospective studies can yield a much quicker result and cost less but often are less reliable and of lower validity. The "power" of cohort studies tends to be dependent on fairly large numbers, particularly if the disease searched for has a low incidence.

Intervention studies are concerned with the observation of an effect on a population, e.g., by reducing a certain exposure, or by altering any other relevant factor.

4.3.4. Usefulness of Occupational Epidemiological Studies

An occupational epidemiological study may be initiated to describe the health status of a particular work population. It may also be used to analyze possible associations of a disease with the place of work or the work environment. It could be used to answer specific questions resulting from findings in animal toxicological studies (mutagenicity, carcinogenicity, etc.), or to assess the validity of existing or planned limit or threshold values for certain substances at the place of work or in the work environment. Under favorable circumstances occupational epidemiological studies can even act as a monitor for the efficiency of protective measures. Occupational medical questions that might be answered by epidemiology are:

What is the morbidity or mortality for workers exposed to a particular substance or agent?

Is there an elevated risk of morbidity or mortality due to a particular disease?

What working history is found for workers who suffer from a particular disease?

What is the significance of certain abnormal laboratory or biological monitoring findings in certain workers, with, for example, elevated urine or blood levels of a particular substance or its metabolites?

The interpretation of an occupational epidemiological study eventually has to be compared with experimental animal and laboratory data, which often may give more precise and reproducible data on dose and effect. Since epidemiology is a descriptive science it concerns itself with humans and helps to evaluate possible effects at exposure levels that are actually experienced in the work environment.

But any occupational epidemiological study can only be as good as the basic data used for it. The interpretation of an epidemiological study is rarely a simple task and should be made within

the epidemiological framework, taking into consideration the findings of similar studies. Therefore, so- called negative studies should also be published whenever possible.

4.4. Ergonomics

4.4.1. Introduction; Definitions

The physiology of work is based on the principles, experiences, and findings of applied physiology. It is the systematic study of the interactions between humans and their work. In particular, the effects of various forms of human work on individual body functions or on the entire human organism are analyzed. The factors studied include time, duration, hardness, difficulties, amount, and monotony of work as well as influence of the surroundings. These effects are then compared with the prerequisites for the performance of the working person.

The performance prerequisites can be differentiated according to the capabilities as structural characteristics of the person:

1) Prerequisites for physical performance, general condition, constitution, acquired physical and mental prerequisites, such as knowledge, experience, skills, and degree of practice and training
2) Prerequisites relating to work, such as powers of vision and hearing, dexterity, etc.
3) Willingness to work as driving and guiding characteristics: advancement orientation, intro- and extroversion, perseverance, satisfaction of needs, striving for a sense of achievement, varying physiological readiness to work as a result of the circadian rhythm, etc. [44], [45]

The goal of the physiology of work is to acquire scientific principles, findings, and rules in order to adapt the various forms of human work to the capabilities of the working person in the sense of preventing strain-induced health damage.

Ergonomics is regarded as an interdisciplinary core area of industrial science. A broad definition is given in [46]: "Industrial science deals with the analysis and organization of work systems and working facilities. The starting point and the goal of this study are the individual and social relationships of the working person to the other elements of the work system."

Therefore, industrial science is the science of:

1) Human work, especially from the standpoint of cooperation with others and interaction with working facilities or objects
2) The prerequisites and conditions under which the work is carried out
3) The consequences and effects of work on people, their behavior, and hence their productivity
4) The factors by which work, its conditions, and effects can be influenced in a humane fashion

Thus, the organization of work according to knowledge of industrial science includes all measures by which the system human and work can be humanely influenced.

These diverse and multifaceted questions can be solved only by the cooperation of the various scientific fields, by using findings based on human work. These fields include:

1) Medicine, especially physiological, hygienic, and pathological aspects
2) Social sciences, especially psychology, sociology, and education
3) Technical sciences
4) Economics and jurisprudence

The terms ergonomics and industrial science are sometimes used synonymously because clear and generally recognized boundaries do not exist, and opinions on the definition of "ergonomics" differ.

However, it can be stated that ergonomics is an integral part of industrial science without completely encompassing the entire field. Numerous problems of social science and sociology and a series of medical areas are not addressed by ergonomics. On the whole, industrial science is regarded as a pure science and ergonomics is more of an applied science.

Ergonomics is increasingly becoming a human- centered systematic science. The results are based on humans and the constructive consequences for technology are also derived from people [47]. The term ergonomics is derived from the Greek *ergon* (work, act) and *nomos* (law, rule, teaching).

The term ergonomics has spread internationally, largely due to the journals *Ergonomics* (since 1957) and *Applied Ergonomics* (since 1969) [48], [49].

The International Ergonomics Association (IEA) was founded in 1959 and represents about 20 national associations [50]. Today, ergonomics includes various branches of industrial science, e.g., anatomic, physiologic, psychologic, medical, and scientific aspects.

Ergonomics has increasingly opened up different spheres of activity and areas of application, including: household articles, traffic including safety aspects, sport, and leisure activities. Only areas of ergonomics that are relevant to industrial medicine are discussed here.

4.4.2. Scope of Ergonomics

The following focal points of ergonomics are worth mentioning:

1) Analysis, measurement, and assessment of human – machine/human – work systems and the determination of the limits of overworking and underworking. In this connection, the stress – strain concept plays an important role.
2) Organization of human – machine/human – work systems with the purpose of adapting the work to the person. This area includes the ergonomic planning and construction of the workplace, working facilities, working surroundings, and hours and structure of work.
3) In an inter-individually and intra-individually varying range (variable time-dependent prerequisites for performance of an individual person), the adaptation of the person to the work is also possible by means of education, practice, habit, training, and rehabilitation measures.

4.4.3. Stress Factors

The stress – strain concept of ergonomics mentioned above includes a large number of influencing factors which act on the working person during the work under investigation. The following factors can contribute to the burden of the working person.

Workplace:	Spatial design, visual conditions, acting forces (e.g., when lifting and carrying loads)
Working facilities:	Indicators and signals, screens, working chairs, handles and actuators, working aids and tools
Work surroundings:	Sounds, vibrations, light (e.g., lighting), and air (e.g., ventilation)
Working hours:	Shift system, flexibility, regulation of breaks
Work structure:	Work content (e.g., enrichment of work) distribution of work (e.g., group work)

The above sequence corresponds to experience gained in production in the processing industries, predominantly in mechanical engineering, the motor industry, electrical engineering, and precision engineering. However, it can also be applied to other areas of work, such as the chemical industry. It has proved to be a suitable basis for examining and developing the main aspects for the ergonomic organization of work [50].

4.4.4. Assessment and Testing Criteria

According to [51], prior to a detailed examination, the following criteria and questions can be used for the assessment of working conditions as a prerequisite for the organization of work.

1st	Criterion:	Feasibility
	Question:	Can the planned work be carried out with the designated persons?
2nd	Criterion:	Endurability
	Question:	Is the work on a permanent basis endurable for the designated persons?
3rd	Criterion:	Reasonableness
	Question:	Are the work and the expected working conditions reasonable?
4th	Criterion:	Satisfaction
	Question:	Will the persons designated for the work be satisfied with the work and the working conditions to be expected [51] ?

An examination of the above criteria is helpful in assessing whether all persons designated for the work are capable of carrying out the specific task planned.

For instance, a certain task cannot be performed if it involves work that must be performed beyond arms' reach. If the strength required exeeds that of the designated persons, this

can be a reason for a task being not performable [50].

The criterion bearableness includes the term "strain". Here, the effect of a specific task on humans is examined. For instance, a given stress does not produce the same strain in all persons.

The demand made on the particular worker depends on individual capabilities, which can vary widely due to, e.g., age, constitution, sex, personal abilities, and skills. Consequently, strain is the individual, psychophysical reaction of the organism to a stress [52]. For the assessment of individual strain, evaluation criteria from industrial medicine are of considerable importance. This applies in particular to handicapped employees. ROHMERT describes strain as a varying degree of exhaustion of individually different capabilities by a given stress [53].

Strain can be technically measured by physiological means, e.g., cardiac rate, changes in blood pressure, body temperature, electromyogram, electrooculogram, or by psychophysiological means, e.g., flicker fusion frequency or selection reaction test. Psychological and sociological strain can also be detected by widening the stress – strain concept, e.g., by means of a questionnaire, interview, strain scaling, and group observation.

This can be explained with the help of a few examples:

Stress by lifting and carrying of weights will lead to strain of the musculo-skeletal and the cardio-vascular systems. The intensity of strain depends on, e.g., posture, individual muscular power, quality of cartilage and intervertebral tissue, the axial conditions of the strained section of the skeleton, e.g., post traumatic faulty alignment, individual patterns of movement, movements required by the specific task (e.g., frequent overhead movements), and on the individual cardio-vascular performance.

The thermoregulation system is strained by the stress resulting from the action of heat when emission of body heat is obstructed, e.g., by working in fully protective clothes, or heat is supplied to the body from the outside. Other factors to be taken into account include the heaviness of the work, working time under the action of heat, the interval between and duration of cooling breaks, and the provision of special clothing. Moreover, the intensity of strain in this example depends on the degree of acclimatization to the working conditions.

A control and supervisory task can require high attention and concentration, especially if the product quality essentially depends on this work. The intensity of strain can depend on a series of individual performance prerequisites, e.g., reactions, experience, routine with regard to the control and supervisory task, and motivation (e.g., avoidance of standstill periods and achievement of the best possible quality).

In the sense of motivation or inhibiton, certain factors can be linked to individual abilities and skills. These factors include working conditions resulting from the subordination or dependency of workers, conditions resulting from the organization of the company, working atmosphere, wages and social benefits, and social and company systems of standardization, control, and sanctioning.

Negative social relationships can represent an additional stress which, because of the resulting strain, can possibly lead to the overtaxing of the individual [52], [54].

In the case of screen work, strain can depend on the amount of work, arrangement and design of the keyboard, the office chair, the quality of the screen, and glare in the field of vision. Here, the individual factors can be further differentiated from the standpoint of ergonomics. For instance, increased demand on the eyes due to impeded focusing (accommodation) can be caused by low resolution of the characters, insufficient contrast between the characters and the background, instability of the characters, reflections on the glass surface of the display, and unsuitable design of characters and typeface [55].

The spatial design of a computer-terminal workplace must take into account the variations of body size. To optimize the design of the workplace, a graphic scale model of the workplace is used into which the schematic depiction of human figures with the different expected body sizes can be inserted. This method is known as somatography [56]. In the meantime, somatographic models and computer aided methods are available, making perspective representations of the spatial situation possible [50].

In many cases, ergonomic findings have already been embodied in law, e.g., the decree and guidelines on workplaces, acknowledged rules of technology in numerous clauses of DIN and

VDI, guidelines of the EC Council on the minimum regulations with regard to safety and health protection, e.g., for working with visual display units and for manual handling of loads (see Sections 2.1, 2.2, 2.3, and 2.4).

The application of ergonomic rules in industrial medicine requires ergonomic assessment of the working conditions and medical assessment of the working person.

To assess working conditions, numerous methods for the analysis of work and stress can be used. These include ergonomic test lists for the evaluation of the state of organization [54], questionnaires for the ergonomic description of working conditions [57], and representations in text books and monographs [47,54,55,58–65]. Moreover, the legally embodied regulations mentioned above must be considered. To assess the working person, industrial medical criteria are to be used. These must be supplemented by the application of biomechanical, neurophysiological, and functional anatomic principles as well as physiological and psychological findings.

4.4.5. Objectives

In health protection at the workplace, ergonomics supports the concept of prevention and helps avoid work-related illness and disease [66].

Attempts should be made to replace corrective ergonomics (subsequent consideration of ergonomic findings and industrial scientific evaluation criteria when, e.g., ergonomic findings have been violated in the planning process) by the concept of prospective ergonomics.

In this concept, Laurig [66] summarizes two meanings of the term "prospective":

1) The possible prediction of future effects of working conditions and their assessment (e.g., the prediction of the limits for the endurability of the effects of vibration)
2) The application of ergonomic findings to the improvement of work productivity (e.g., the design of lighting conditions to improve quality)

In principle, for the application of the concept of prospective ergonomics, it is true that both ergonomic and industrial-medical organizational objectives must always be established in connection with the definition of production engineering planning objectives. In this process, the regulations of public occupational safety and of the trade association must be taken into account (see Sections 2.1, 2.2, 2.3, and 2.4).

Consequently, this priority can also result in restrictions on decisions preferred from a production engineering standpoint if these cannot be made compatible with the criterion of harmlessness.

Therefore, ergonomic findings should always be taken into account in the planning of human – machine/human – work systems. Only in this way can it be guaranteed that a workplace need not to be changed after it has been set up [50].

4.5. Evaluation of Health Risks [67–72]

The American National Academy of Sciences has defined health evaluation of persons exposed to chemical compounds as:

"The scientific activity of evaluating the toxic properties of a chemical and the condition of human exposure to it in order both to ascertain the likelihood that exposed humans will be adversely affected, and to characterize the nature of the effect they may experience" (1982).

Before the health risk of a particular task or exposure can be evaluated, terms such as "health" and "risk" must be defined, to arrive at a reliable balance and conclusion.

4.5.1. Basic Considerations

The state of health of an individual is in no way a static entity. It is a dynamic balance between the inborn potential of the human body and external, environmental factors (i.e., the balance between capacity and burden of an individual). Every biological alteration may disturb or change the balance. For instance, age is a biological factor that continuously influences the capacity of an individual.

A second problem in the evaluation of health risks is the meaning of the phrase "risk". Risk is a combination of the chance and nature of health impairment due to exogenic factors, caused by

a particular action or event. It is difficult to outline a universally applicable framework for the phrases "risk" and "safety", because they are largely determined for individual cases.

Since there is no life without risk, which kind and degree of risk is accepted or tolerated as inherent to normal life, and therefore not be considered as risk, differs from person to person and situation to situation. Each person will, intentially or intuitively, create his own framework of safety that embodies the acceptance of a particular chance and extent of disability or harm.

Thus inter-individual evaluation of a particular hazard may vary in nature and intensity, according to whether it is an activity performed by oneself or another person. Smokers accept the risk of dying early from lung cancer, whilst passive smokers do not accept harmful effects from inhaling cigarette smoke produced by other persons.

A sensible definition of health with respect to medical checks on individuals might be: "the absence of objectively and/or subjectively perceivable signs that are considered to be harmful".

However, when using this operational definition, another problem is introduced: the question to what extent a particular finding must be considered harmful or not.

Also, from a medical point of view, not every response of the body due to a particular external physical and chemical agent should by definition be considered as harmful or impairing to health. The human body responds in one way or another to all types of endured burden. The nature and intensity of the burden is largely decisive for the nature and intensity of the response.

Increased physical burden on performing strenuous physical work, for instance, induces increased oxygen demand of the muscular tissue. This is compensated for by faster and more intense transport of oxygen from the lungs to the tissues. This compensation mechanism includes the intensivation of respiration and increased heartbeat. As soon as the burden becomes too high, these mechanisms become insufficient, and functional decompensation follows. The incidence of decompensation must be regarded as medically unacceptable and harmful, unless it is readily reversible when exposure ceases, and reconvalescence can be expected within a short time.

The working capacity of the human body mainly depends on the intrinsic, inborn properties but also on other, external stresses.

This principle of individual capacity and load also holds for chemical exposures. Contact with and exposure to chemicals may cause local and/or systemic effects.

Local effects can be caused by physical contact of the skin, eyes, or mucous membranes with certain chemicals. Contact with acids and alkalis, in particular, may cause such local effects, but also other compounds, such as aldehydes (e.g., formaldehyde) and ketones may cause local harm.

Systemic effects can result from uptake of a compound via the lungs, the digestive tract, or through the intact skin and mucous membranes.

The nature and extent of uptake depend mainly on compound-related properties such as volatility and solubility and the exposure circumstances. Some examples that illustrate this are:

1) During spraying of the volatile soil and space fumigant bromomethane large amounts can be inhaled if proper respiratory protection devices are not used. But even when inhalation is not possible, large amounts of liquid and vapor can be absorbed through unprotected skin.
2) The oily liquid aniline with only minor volatility, is easily absorbed through intact skin.
3) Dimethylformamide is a high-boiling bipolar solvent with hepatotoxic (livertoxic) potential. The percutaneous absorption rate is fast and high. Thus, exposure to DMF vapors far below the threshold limit values do not guarantee the absence of harmful effects when handling this solvent.

4.5.2. Difficulties in Interpretation

The systemic response, which may or may not be clinically apparent, can also be regarded as a physiological response as long as the extent of uptake of the chemical does not exceed the compensatory capacity of the human body. The most important compensation mechanisms for chemical agents are detoxification and elimination.

A sharp distinction between biological response and harmful, pathological effects cannot

always be made. Therefore, interpretation differences between experts concerning evaluation of data are possible.

For some phenomena, such as chromosome aberration, the biological composition of semen, and some electrophysiological responses of muscle tissue and peripheral nerves, insufficient knowledge is available about normal inter- and intra-individual biological variations. An increase in the number of chromosome aberrations and a decrease of the number of healthy spermatozoa in the semen in response to the uptake of a particular chemical must not à priori be considered harmful to health.

Increased production of an enzyme that interacts with a particular chemical may follow prolonged exposure to that chemical. This enzyme induction can be regarded as a physiological response to a particular chemical burden. In some cases enzyme induction leads to better and faster detoxification and is an efficient defense mechanism against a chemical burden. However, there is still difference of opinion between experts whether enzyme induction should be regarded as an unacceptable effect or a normal response of the human organism to exogenic chemical stresses.

To arrive at a consensus, it is imperative to attain uniformity in the judgement of health risks. When this cannot be realized, a compromise should be accepted by all parties than can be expressed in a operational limitation between physiology and pathology.

Another difference of opinion between experts in the assessment of health risks might arise about the significance of impairment of health. Also, consensus should be sought about the nature and intensity of impairment that will be considered harmful.

4.5.3. Dose/Effect/Polymorphism

The intrinsic harmful properties of a chemical are determined by its inherent properties. Most effects on the human organism due to exposure to chemical compounds satisfy the principle of dose-dependency of effect. This holds that for almost every response to the uptake of a chemical, a no effect level and/or a no adverse effect level exists. It implies that in principle every chemical, under defined conditions, in a defined quantity and route of administration, and in some or all exposed individuals may cause harmful effects. This principle was discovered and published by the alchemist PARACELSUS as early as the 1500s.

An exception to this rule concerns genotoxic chemicals. For a proper preventive policy, when no contradicting data are available, it must be assumed that all concentrations of these particular chemicals, even in molecular quantities, may initiate a carcinogenic or mutagenic process after entering the cell.

However, in reality this appears to be too stringent. Firstly, it may only be valid for chemicals that have not been detoxified before reaching the organ cells. And secondly, living species have a great capacity for repairing DNA damage in cells.

The toxicological risk for an individual of contact with a chemical depends on (1) the intrinsic properties of the chemical, (2) the impairing potential (toxicity), (3) the exposure conditions, and (4) a number of person-related factors. In particular factors such as age, gender, and life-style (smoking, alcohol consumption, eating habits) may influence both the nature and intensity of an effect. This also holds for genetically determined differences in the availability of particular enzymes or in tissue susceptibility.

It is well known that a fairly large part of the global population has insufficient amounts of the enzyme *N*-acetyltransferase to guarantee optimal detoxification of aromatic amines via noncarcinogenic metabolic pathways.

Another example is the congenital deficiency of glucose-6-phosphate dehydrogenase (G 6 PD) in some ethnic groups. This enzyme is necessary for the metabolic reduction of organic peroxides. G 6 PD deficiency can lead to serious damage to the membranes of red blood cells, followed by extensive internal hemorrhage, after uptake of peroxide-forming chemicals, because these peroxides are reduced too slowly.

Although a number of inter-individual differences in biochemical capacity can be well explained, the cause of a number of these differences is still unclear. Therefore, in every estimate of health risks, the possibility should be reckoned with that a small number of a population will respond to exposure to a particular chemical, quantitatively or qualitatively, in a manner other than the majority.

Especially in setting exposure limits for chemicals, the existence of particular risk factors or risk groups, should always be considered.

The estimate of health risks of a particular activity or exposure to a particular harmful agent during work passes through the following phases [68]:

1) Hazard identification
2) Risk estimation
3) Risk evaluation
4) Risk limitation

4.5.4. Hazard Identification

The initial phase of a health risk assessment includes inventarization and description of all components of an activity to establish qualitatively whether there is a health risk due to conditions and influences at work.

A detailed study should be made of the nature of work and of the workplace. The inventory should include a full list of chemicals to be used, their physical and chemical characteristics (e.g., volatility, solubility, flammability, explosivity) and toxicity.

Toxicity. Information on toxicity can be derived from

1) Human experience with the compound
2) Results from animal experiments

Data on the state of health of humans who have been exposed to a particular compound in the past must be carefully collected and evaluated to obtain relevant information. Human experimentation is restricted, stringently regulated, and rarely acceptable. So, almost all human effects due to chemical exposure are only observational and descriptive.

The aim of this kind of investigation is to obtain knowledge about dose – effect relationships. For this reason, knowledge as accurate as possible concerning the extent of past exposures is essential. Unfortunately, this condition causes major problems because in the past measurements have not been performed at all, not on a regular basis, or by means of an unreliable or insensitive method (see Section 4.3).

As reliable data on previous exposures are often not available for estimating the toxicity, the assessment must be based on the results of animal experiments.

Animal experiments have the advantage that the exposure to a single compound can be controlled with respect to nature, dose, and duration. Thus, confounding influences, such as simultaneous exposures to other chemicals and life-style factors, can be avoided.

A major drawback, however, may be differences in susceptibility between human and animal species. Therefore, the use of an animal species that best mimics human metabolism is recommended. However, in many cases the most elementary knowledge for making a reliable choice is lacking.

Due to metabolic differences between species and sometimes in different strains of the same species, fundamental differences in detoxification and elimination mechanisms may be possible.

This can be illustrated by the following examples:

1) The human carcinogen β-naphthylamine does not give a carcinogenic response in assays with rats and rabbits
2) Mice respond with malignant liver and lung tumors in long-term inhalation assays with dichloromethane, whereas in rats only males show benign fibro-adenoma in mammary glands
3) B 6 C 3 F 1 and C 3 H mice strains are highly susceptible to spontaneous liver carcinoma. In males hepatic tumor incidence is ca. 30 % and in females ca. 6 %. With the same treatment in mice of the C 57 BL/6 J strain, induction of liver tumors does not occur [72].

Until now no generally accepted method for bridging inter- and intra-species differences is available. Only when a good qualitative and quantitative understanding of the toxicokinetics of a compound exists with respect to the metabolic pathway can a valid translation from animal to human be made. In case of doubt, uncertainty in the extrapolation can be compensated by using safety factors or uncertainty factors. The magnitude of these factors can vary from zero to several thousand, depending on the intended extent of certainty that no harmful effects will occur. The choice of magnitude of a safety factor is arbitrary, but is always related to the nature, quantity, and quality of the available

data. The greater the knowledge gap, the greater is the safety factor.

4.5.5. Risk Estimation

The qualitative inventory of risk factors is followed by a quantification of these factors. For this phase a clear understanding of the dose–effect relationship is indispensible. As sufficient relevant and valid data are often lacking, the risk estimation is often an educated guess or "guestimate".

A second activity during this phase is the assessment of the nature of the exposure. Is it a single, short-term or a long-lasting, chronic exposure? What is the magnitude of the exposure?

Also the nature of interaction between simultaneously acting chemicals should be determined, as well as the influence of other environmental conditions and individual- or grouprelated factors. For this reason, the nature of the environmental air at the working place and the magnitude of the concentrations should be estimated as accurately as possible. For details on analysis and monitoring strategies, see Section 3.3.

4.5.6. Risk Evaluation

The third phase of a risk assessment procedure deals with the compilation of the data collected during the two previous phases. This compilation may lead to a conclusion about the potential health damage of a defined population due to a defined activity and about the chance that the damage will actually happen. It is a matter of political considerations whether this estimated risk is acceptable or not. In a number of situations it can be estimated whether the risk is in compliance with actual or optional limit values.

4.5.7. Risk Limitation

Based on knowledge of the likelihood, the nature, and seriousness of potential health risks a program can be designed to prevent harmful health effects completely or to reduce the chance of health risks as far as possible.

The nature and the extent of preventive measures depend on the technological possibilities on the one hand, and on political, social, and economical considerations on the other. Tightening the limits of risk acceptance always results in more expensive preventative programs. Therefore, a balance between technical and economical feasability is indicated. Which precautionary measures can be taken is discussed in Section 4.1.

4.6. Occupational Diseases and Work-Related Illnesses [73–76]

4.6.1. Introduction; Definitions

A variety of factors at the workplace can effect human health and cause health impairment, illness, and disease.

More than 4000 years ago the ancient Egyptians described certain illnesses linked to specific jobs or professions (see Chap. 1). Since then knowledge about the negative effects of factors from the working environment on human health has increased tremendously. The continuous advance in medical science and the ongoing improvement in diagnostic techniques has fostered the identification of occupational diseases and work-related illnesses.

An occupational disease is "a disease caused by any physical factor, chemical substance, or biological agent encountered in the course of work under a contract of employment" [74]. It must be established by scientific means that the disease can be caused by the factor under consideration and the worker must have been exposed seriously to this factor during his work. The exposure generally must persist over a long period of time, and the adverse health condition develop as a chronic disease.

The term work-related illnesses covers all situations of ill health that are triggered or aggravated by influences at work. They may be acute and curable, or chronic. In practice, the term is used to characterize illnesses that are not covered by the term occupational disease.

4.6.2. Occupational Diseases

Occupational diseases are classified in various subgroups.

Each disease caused by a specific agent exhibits characteristic symptoms which are the basis for its identification.

The largest group of causative agents are chemical substances. Chemicals that are known to be capable of causing occupational disease include the following elements and their compounds

Arsenic
Beryllium
Cadmium
Chromium VI
Cobalt
Fluorine
Lead
Manganese
Mercury
Nickel
Phosphorus
Vanadium
Zinc

and the following compounds

Aromatic amines
Benzene and homologes
Carbon disulfide
Carbon monoxide
Halogenated aliphatic hydrocarbons
Halogenated aromatic hydrocarbons
Hydrogen sulfide
Nitro derivatives of aromatic hydrocarbons
Phenols, their homologues, and halogenated derivatives

Occupational lung diseases caused by dust or fiber exposure are regarded as a special group. Occupational diseases caused by dusts and fibers are:

Asbestos	asbestosis
Quartz	silicosis
Certain metal dusts	pneumoconiosis

Certain physical specifications are required (specific fiber size for asbestos, crystalline dust for quartz).

Here the disease is caused either by chemical effects, mechanical impact, and in some cases allergic reactions, or by a combination of these effects.

Another specific group of chemically induced illnesses are asthmatic disorders and allergic skin effects. The most prominent causative agents for occupational allergies and their target organs are summarized in the following:

Chromium	skin
Animal hair	respiratory tract
Flour	skin, respiratory tract
Isocyanates	skin, respiratory tract
Nickel	skin
Penicillin	skin, respiratory tract

Most compounds can cause both skin and respiratory sensitization.

With allergic occupational diseases, early detection of the cause – effect relationship and consequent avoidance of any further exposure to the allergen is of major importance for the further course of the disease. The severity and irreversibility of the health impairment is directly correlated with the duration of exposure after the onset of allergy.

Since the first description of scrotal skin cancer in chimney sweeps by Pott in 1775 a number of chemicals have been identified that can cause occupational cancer.

The connection between exposure to chemical agents at the workplace and cancer development in humans has been definitely established for the following substances:

4-Aminodiphenyl	bladder cancer
Arsenic	skin cancer
Asbestos	lung cancer, mesothelioma
Benzene	leukemia
Benzidine	bladder cancer
Bischloromethyl ether	lung cancer
Calcium chromate	lung cancer
Coal tars and pitches	skin cancer
2-Naphthylamine	bladder cancer
Vinyl chloride	liver cancer (hemangiosarcoma)

Occupational diseases can also be caused by physical agents such as noise, ionizing radiation, high pressure, heat, and vibration. The related diseases are:

Ionizing radiation	bone marrow damage, skin changes
Noise	hearing deterioration
Overpressure	divers' disease
Vibration	white finger syndrome

Another group of occupational diseases can be caused by biological agents. This group includes infectious diseases and parasitic disorders acquired during work with infectious agents

or in areas where infection is enhanced by climate or other conditions. Bacteria, viruses, and parasites can cause diseases in this group.

For most occupational diseases no specific therapy is available except for those caused by biological agents, where therapy with antibiotics can often cure the disease.

Some of the diseases continue to progress even after the exposure to the causative agent has been stopped. Classical examples for this are some of the pulmonary diseases caused by dust, such as beryllosis and silicosis.

Occupational cancer normally develops after a latency period of 15 – 40 years after first exposure to the causative agent. Workers with known exposure to human carcinogens should therefore be observed even after retirement in order to detect the cancer as early as possible.

In most European countries and North America, as well as in some other countries throughout the world, occupational diseases are compiled in a national list, which is generally the basis for possible compensation [73], [74].

4.6.3. Prevention

The prevention of occupational diseases is one of the most important tasks in occupational health and safety.

All groups of professional experts must cooperate with employers and employees to avoid adverse conditions at work that could cause occupational diseases. Of special importance is the medical surveillance (see Section 4.1) and the control and improvement of hygiene at the workplace.

Technical means and substitution of known hazardous chemicals (e.g., carcinogens) as well as providance and proper use of personal protective equipment are important tools in prevention of occupational diseases.

4.6.4. Compensation for Occupational Diseases

In the states throughout Europe and North America, as well as in an increasing number of countries in other parts of the world, recognition of occupational diseases and compensation for resulting disability is regulated by national laws.

An important basis for compensation is the respective national list of occupational diseases. Within the European Union a proposal for a European list of occupational diseases has been issued, and attempts to harmonize the legal basis for occupational diseases throughout the European Union will continue [75].

The World Health Organisation (WHO) has also issued a list of occupational diseases, which can be used by states that have not yet established a national list. The existing national lists of occupational diseases show large variations in classification, scope, and number of diseases listed.

The basic condition for the recognition of a disease as occupational is

1) Proof of sufficient exposure to the causative agent
2) Scientific proof that the disease in question can be caused by that agent

The mode of compensation differs from one country to another. In some countries standardized rules govern the amount of compensation.

In Germany, for example, compensation for an occupational disease is only granted if it causes a disability of 20 % or more. Below that margin the occupational disease is recognized as such but without compensation [73].

In the United States compensation is granted under diversified rules in the different states, based upon state legislation. The U.S. federal list of occupational diseases is modified at state level. Thus a wide variety of conditions governs the question of compensation for occupational diseases [76].

In several states, including the United States, Germany and other European countries, diseases can be recognized and compensated as occupational even if they are not contained in the national list, provided that:

1) The disease is causally related to a hazard at the workplace
2) The claimant has been exposed to the causative agent by reason of his employment
3) The incidence of the disease is substantially greater in that specific industry/occupation than in the general population

By this provision new occupational diseases can be discovered and compensated, and later included in the national list.

The most important tool for discovery of new occupational diseases is epidemiology (see Section 4.3).

Compensation for occupational diseases and related disability is provided in different countries under the national legislation either by a specific insurance fund, by government funds, or directly from the employer. Depending upon the respective legislation it can be payed as a lump sum or provided as a monthly pension.

For several occupational diseases compensation is granted only if the employee is not able to continue work in his former profession. Under German legislation this is the case of irritative and allergic disorders of the pulmonary tract and of the skin as well as for the newly established occupational diseases of the cervical and lumbar spine.

Under these circumstances the statutory accident insurance institutions in Germany (Berufsgenossenschaft) provide the financial means for training in a new profession.

This possibility is also available early on even if the occupational disease is not yet compensable but is expected to progress if work under the causative conditions continues.

4.6.5. Trends

The continuing development in medical diagnostics and epidemiology is providing new information on the possible cause – effect relationship for illnesses or diseases so far not recognized as occupational disease.

Areas under research and discussion are certain orthopedic diseases like chronic diseases of the spine; repetitive motion trauma (RMT), e.g., tendovaginitis; neurological disorders in connection with a number of organic chemicals (mainly solvents); and stress-related health impairments, including myocardial infarction triggered by stress at work. Further research and epidemiological studies will help to clarify these questions.

4.6.6. Work-Related Illnesses

Whereas occupational diseases mostly develop under chronic influence of the causative agent and are of persistant nature, work-related illnesses can be caused by acute or chronic exposures and are often fully reversible with adequate therapy and cessation of exposure. The scope of illnesses covered under this term is under discussion and covers acute infections as well as acute effects by chemical agents and acute disorders of the musculo-skeletal system, or health impairments related to shift work. Aggravation of preexisting ailments by influences at work is also covered by this term.

So far there is no systematic categorization or compensation. In some instances repeated acute illnesses of the same kind can lead to chronic occupational disease and in turn to compensation. Again the prevention of adverse influences at work is the best way to avoid adverse health effects. Frequent workplace inspections and evaluation of working conditions by the occupational physician and the industrial hygienist are of major importance for prevention, as is occupational medical surveillance for early detection of work-related illnesses.

4.7. First Aid

Basic Principles. In the case of occupational accidents, the medical care given must follow the same principles as at the communal level. The individual therapy steps taken to prevent life-threatening emergencies must be adapted to the particular requirements and must be well coordinated. The prerequisite for this is a well-functioning rescue chain consisting of the following four links:

1) Initial care at the site of the accident
2) Observation during transport
3) Initial care in the clinic
4) Final care in the clinic

This section discusses the measures necessary at the accident site.

Basic Requirements in the Companies. In Germany, the accident insurance institutions (trade associations) demand certain precautionary measures from the employers. Producing companies must train 10 % of their workers in first aid. In the case of shift work, one person trained in first aid should be present on each shift. In clerical work, 5 % of employees should

be trained in first aid. This training is conducted by organizations authorized by the trade associations. The basic course includes heart – lung resuscitation. A refresher course must be taken after two years at the latest.

Companies must have alarm systems to call the rescue units immediately and lead them to the site.

In the case of contact with chemical products, the victims must be showered immediately. Companies must be equipped with the necessary emergency showers and eye-washing devices. First aid for accident victims includes the application of an emergency dressing. Depending on the number of employees, first aid boxes of various sizes must be kept ready in suitable containers that are quickly reached and readily accessible.

Rescue of Accident Victims. When freeing workers who are trapped or have fallen, the actual rescue measures are taken by the fire fighters. The fire brigades must have available all the technical facilities required for rescuing accident victims. Workers contaminated by chemical substances must be removed from the danger zone as quickly as possible. In case of a gas cloud, for example, they must be removed at right angles to the wind direction. The rescuers may be coworkers or firemen who have arrived at the site; they must protect themselves from contact with the substances.

The rescue equipment includes not only breathing masks and compressed air masks, but also protective clothing. Exhalation of toxic substances, such as hydrogen cyanide, carbon monoxide, or solvents, can be dangerous for the rescuer during mouth-to-nose respiration. Accident victims must be immediately freed of clothing contaminated with the product. The rescuers must wear gloves to protect themselves from skin contact. Victims should be undressed under running water, if possible. Contaminated clothes must be safely disposed of.

Maintenance of Vital Functions. The vital functions of each accident victim must be checked before he is transported. In case of respiratory arrest and/or circulatory arrest, reanimation measures must be taken immediately by the colleagues trained in first aid, with the support of medically trained firemen.

The doctor on emergency call continues the life-saving therapy, determines when the patient can be moved, and accompanies the victim to the hospital.

Product Removal. In case of skin contact, chemical substances must be removed immediately. Every second counts, especially if the victim has been burned with, e.g., hot phenol or hydrofluoric acid.

Workers must be informed about how and where they can reach the next washing facility. The primary measure is washing with copious water for several minutes, possibly with the additional use of soap. In all chemical companies which work with hazardous substances, shower facilities must be installed at certain key positions, where the accident victims can shower immediately. This helps to reduce the damage caused by all products, especially if water-soluble substances are involved. However, even sparingly water soluble products can be washed off by this purely mechanical measure.

For certain products, special neutralizing agents should be made available:

Hydrofluoric acid	calcium gluconate gel, calcium gluconate solution
Aromatic nitro and amino compounds	poly(ethylene glycol) 400
Phenols, cresols	mixture of ethanol and poly(ethylene glycol) 300 (1 : 2)
Chromium	ascorbic acid

In case of exposure to such products, a thorough aftertreatment/neutralization must be carried out in the company-owned accident department.

For neutralization, acetic acid (0.3 %) can be used for alkaline substances, and sodium acetate solution (0.3 %) for acids. Repeated testing with pH indicator paper is required to ensure that neutralization is complete.

The hair, finger nails, and ears deserve special attention. Hardened plastics must be mechanically removed.

The eyes are severely endangered in chemical accidents. The eyes must be rinsed directly at the site of the accident, and rinsing continued during transport.

Water should generally be used as the rinsing agent because of the wide range of products in most companies. In the company accident de-

partment, this preliminary treatment of eye burns is continued after the application of anesthetizing eye drops. A special neutralizing solution can be used.

Treatment. In treating victims of chemical accidents, symptomatic measures must generally be taken. Special antidotes exist only for very few chemicals. The following antidotes are permitted in Germany:

Chemical substance	*Antidote*
Acrylonitrile	*N*-acetylcysteine
Aromatic nitro and amino compounds	vitamin C and toluidine blue
Hydrogencyanide and cyanides	sodium thiosulfate and 4-dimethyl-aminophenol
Carbamates	atropine
Chromic acid, dichromates	vitamin C
Hydrofluoric acid	calcium gluconate, magnesium sulfate
Methanol	ethanol and folic acid
Phosphoric acid esters	atropine and toxogonin
Irritant gases	glucocorticoids
Hydrogen sulfide	4-dimethylaminophenol

Toxic pulmonary edema caused by inhalation of irritant gases such as phosgene must be treated directly in the inital stage. In addition to the administration of glucocorticoids, positive pressure ventilation improves the success of the treatment. The clinical latent phase, i.e., the interval between the accident and the appearance of clinical symptoms, is of varying length. In case of individual pulmonary irritants, it can last up to 24 h.

Toxic pulmonary edema can be radiologically detected in the early phase, between 6 and 8 h after the inhalative trauma, before clinical symptoms will appear. The duration of the latent phase mainly depends on the dose inhaled. The higher the dose, the shorter is the latent phase.

Prevention. First aid measures must be well organized in each company. Furthermore, the rescue chain must function smoothly. It must be constantly checked whether the necessary precautions have been taken in the company. Regular practice with the simulation of possible accidents improves the effectivity. The antidotes for certain types of poisoning should be kept ready in special therapy containers to minimize the time between the accident and the start of treatment. Regular schooling of employees, efficient training of medical staff, and technically perfect equipment help to minimize damage.

4.8. Occupational Medicine in the United States

Occupational medical programs in the United States function similarly to those in Europe with the exception that U.S. programs extend beyond the workplace conditions. Overall general health and wellness programs are included in addition to health examinations and biological monitoring.

Biological exposure indices provide a tool for assessing workers exposure to chemicals, in addition to workplace air monitoring. Biological monitoring can be required by regulatory standards or recommended guidelines in the evaluation of potential health hazard. Biological exposure indices (BEIs) provided by the American Conference of Government Industrial Hygienists are reference values usually measured in exhaled air, urine, and blood.

Biological monitoring is subject to normal biological variability and requires multiple samples over a period of time to reduce the effects of variable factors. Interpretation of biological monitoring should be with professional judgement and compared to workplace air monitoring and nonwork activities. Legal considerations are necessary when designing such monitoring programs in the United States. Health risk assessment is increasingly important and the basis for recent developments of major regulations and legislative proposals in the United States.

The American Industrial Health Council (AIHC) has made fundamental recommendations for preserving the scientific credibility of risk assessments to improve the role of science in decision-making for protection of workers' health and public health.

AIHC's proposals include having an active process to update current existing guidelines with full weight-of-the-evidence to incorporate new data and methodology. Also, the legislation should promote input from all interested parties including the general public, and should lead to meaningful communications to managers, workers, and the public.

Government-wide risk assessment practices should be considered under the Office of Sci-

ence and Technology Policy to avoid different regulatory agencies having different interpretations from a single data base. The International Program on Chemical Safety (IPCS) is also discussing issues related to risk assessment harmonization. IPCS is coordinating the attainment of a common frame for risk assessment and is working to improve risk assessment methodology in the areas of reproductive/development toxicity, genotoxicity, and carcinogenicity (see Section 4.5).

Epidemiological studies have a special relationship to risk assessment. These studies are normally developed to investigate associations between health effects and a contributing factor. Comparisons between exposed and nonexposed groups can establish associations between exposure and health effects (see Section 4.3).

However, many epidemiological studies do not have the adequately quantified exposures which are necessary for risk assessment methods.

Retroactive studies have limitations because of confounding exposures and numerous health effects. Animal studies can be evaluated for similarity in response, but special attention must be given to species susceptibility, response of target organ mechanisms, and dose response.

Well-designed epidemiological studies are always preferable to animal studies for the risk assessor, due to the advantage of observing dose – response results in humans rather than extrapolating animal results to humans.

In general, for prevention of occupational diseases (risk management) the recommended concentrations for threshold chemical effects use safety factors, while zero threshold chemicals require establishing acceptable concentrations with risk assessment methods.

1. Introduction

At present, there is a lack of comprehensive data on the transport of dangerous goods, in terms of transport volume, transport capacity, carriers, dangerous goods (including dangerous wastes), accident frequency and causes, nature and extent of releases of material because of accidents, leakages, and recovery, etc. The same is true for the area of storage and transport-dependent intermediate storage of dangerous materials and for comparative surveys, e.g., strategies for transport avoidance and traffic deflection as well as site contingency plans. The EC Green Paper on the Effect of Traffic on the Environment makes the following points:

1) An enormous increase is expected in total carriage, average distances, frequencies of consignments, and speed [1]
2) From 1990 to 2010, a 42 % increase of the carriage of goods by road and a 33 % increase is expected by rail [2, 3]
3) Transport of dangerous goods involves extensive risks, especially potential effects on the environment [4]
4) A package of measures for the reduction or avoidance of risk during the transport of dangerous goods has been prepared [5], which sets out the environmental, traffic policy, and economic dimensions of these trends

Comparable forecasts for individual Member States, e.g., Germany, predict a large increase both of goods traffic volume and of transport capacity over the next two decades [6], the proportion of dangerous goods in rail traffic being estimated as ca. 12.4 – 13.8 % and in road traffic as 9.1 – 9.6 % [7]. A breakdown of shipments of dangerous goods by transport sector shows that ca. 27.4 % go by inland waterways, 25 % by road transport (long-distance and short hauls across frontiers), ca. 24 % by sea, and 23.5 % by rail [8].

A forecast of the traffic volume and its distribution, which shows the percentage change compared with 1988, assumes a growth in long-distance road transport of goods of 72.9 % by the year 2010; in inland waterway transport 35.3 %, but in rail transport (less polluting than by road) a reduction of 7.3 %.

Moves toward economic integration of Europe should influence the scale of macroeconomic activity in the short, medium, and long term; this should result in a rise in the demand for transport services. With the increase of freight traffic volume, the number of shipments of dangerous goods inevitably rises, and with it the risk of accidents and release of hazardous materials. There is a consequent rise in other external costs (e.g., destruction of the landscape, pollution, and noise) which differ from each other according to the mode of carriage.

The following global goals can be derived from the forecasts outlined above:

1) Increase of transport safety, including transport avoidance strategies
2) A consistent emphasis on precautionary traffic measures.

A multitude of detailed regulations, constantly updated and amended, are aimed at minimizing the special risks of the transport of dangerous goods. However, most regulations – aside from the UN Recommendations – are specific to a particular mode of transport. In some cases, they have different legal status, different member or signatory states, different geographic areas of application, and to some extent different content. Above all, implementation of regulations in different countries may depend on national interest, the external environment, and geographic region.

However, these regulations do not address the long-term transport policy and environmental challenges of goods outlined above, and are often incomprehensible to the nonexpert and difficult to enforce. Even the UN Recommendations fail to deal with the necessity of transport avoidance and the transfer of consignments of dangerous goods to safer or environmentally beneficial means of transport. The basic issue of classification of dangerous materials and goods is still far from being resolved. The worldwide harmonization of dangerous goods regulations is to be encouraged, but it must not lead to a downgrading of safety and environmental standards, especially under the influence of commercial competition. Undifferentiated harmonization can threaten national instruments, in some cases tried and true, for improving transport safety and guaranteeing precautionary environmental protection, e.g., traffic deflection regulations and the allocation of special routes for certain dangerous goods.

It is also necessary to eliminate distortions of competition between carriers, frequently at the expense of safety and environmental considerations, and to resolve conflicts of aims, e.g., between the freedom of service-rendering and legitimate safety interests, or between interests of transport and environmental policy (assistance or avoidance strategies for transport).

The development of a sufficiently differentiated, yet nationally and internationally coordinated safety culture oriented toward prevention is therefore essential.

2. Safety

Although modern technology has overcome many natural dangers (predators, famines, diseases), it has introducted dangers that were unknown in the past. For example, it is estimated that there are about 100 000 dangerous substances, increasing by 1000 every year.
